Library of Congress Cataloging-in-Publication Data

Encyclopedia of artificial intelligence / Juan Ramon Rabunal Dopico, Julian Dorado de la Calle, and Alejandro Pazos Sierra, editors.
p. cm.

Includes bibliographical references and index.

Summary: "This book is a comprehensive and in-depth reference to the most recent developments in the field covering theoretical developments, techniques, technologies, among others"--Provided by publisher.

ISBN 978-1-59904-849-9 (hardcover) -- ISBN 978-1-59904-850-5 (ebook)

I. Artificial intelligence--Encyclopedias. I. Rabunal, Juan Ramon, 1973- II. Dorado, Julian, 1970- III. Pazos Sierra, Alejandro.

Q334.2.E63 2008

Contents

by Volume

Volume I

| | |
|---|----|
| Active Learning with SVM / <i>Jun Jiang, City University of Hong Kong, Hong Kong; and Horace H. S. Ip, City University of Hong Kong, Hong Kong</i> | 1 |
| Adaptive Algorithms for Intelligent Geometric Computing / <i>M. L. Gavrilova, University of Calgary, Canada</i> | 9 |
| Adaptive Business Intelligence / <i>Zbigniew Michalewicz, The University of Adelaide, Australia</i> | 16 |
| Adaptive Neural Algorithms for PCA and ICA / <i>Radu Mutihac, University of Bucharest, Romania</i> | 22 |
| Adaptive Neuro-Fuzzy Systems / <i>Larbi Esmahi, Athabasca University, Canada; Kristian Williamson, Statistics Canada, Canada; and Elarbi Badidi, United Arab Emirates University, UAE</i> | 31 |
| Adaptive Technology and Its Applications / <i>João José Neto, Universidade de São Paulo, Brazil</i> | 37 |
| Advanced Cellular Neural Networks Image Processing / <i>J. Álvaro Fernández, University of Extremadura, Badajoz, Spain</i> | 45 |
| Agent-Based Intelligent System Modeling / <i>Zaiyong Tang, Salem State College, USA; Xiaoyu Huang, University of Shanghai for Science & Technology, China; and Kallol Bagchi, University of Texas at El Paso, USA</i> | 51 |
| AI and Ideas by Statistical Mechanics / <i>Lester Ingber, Lester Ingber Research, USA</i> | 58 |
| AI Methods for Analyzing Microarray Data / <i>Amira Djebbari, National Research Council Canada, Canada; Aedín C. Culhane, Harvard School of Public Health, USA; Alice J. Armstrong, The George Washington University, USA; and John Quackenbush, Harvard School of Public Health, USA</i> | 65 |
| AI Walk from Pharmacokinetics to Marketing, An / <i>José D. Martín-Guerrero, University of Valencia, Spain; Emilio Soria-Olivas, University of Valencia, Spain; Paulo J.G. Lisboa, Liverpool John Moores University, UK; and Antonio J. Serrano-López, University of Valencia, Spain</i> | 71 |
| Algorithms for Association Rule Mining / <i>Vasudha Bhatnagar, University of Delhi, India; Anamika Gupta, University of Delhi, India; and Naveen Kumar, University of Delhi, India</i> | 76 |

| | |
|--|-----|
| Ambient Intelligence / <i>Fariba Sadri, Imperial College London, UK; and Kostas Stathis, Royal Holloway, University of London, UK</i> | 85 |
| Ambient Intelligence Environments / <i>Carlos Ramos, Polytechnic of Porto, Portugal</i> | 92 |
| Analytics for Noisy Unstructured Text Data I / <i>Shourya Roy, IBM Research, India Research Lab, India; and L. Venkata Subramaniam, IBM Research, India Research Lab, India</i> | 99 |
| Analytics for Noisy Unstructured Text Data II / <i>L. Venkata Subramaniam, IBM Research, India Research Lab, India; and Shourya Roy, IBM Research, India Research Lab, India</i> | 105 |
| Angiographic Images Segmentation Techniques / <i>Francisco J. Nóvoa, University of A Coruña, Spain; Alberto Curra, University of A Coruña, Spain; M. Gloria López, University of A Coruña, Spain; and Virginia Mato, University of A Coruña, Spain</i> | 110 |
| ANN Application in the Field of Structural Concrete / <i>Juan L. Pérez, University of A Coruña, Spain; M^a Isabel Martínez, University of A Coruña, Spain; and Manuel F. Herrador, University of A Coruña, Spain</i> | 118 |
| ANN Development with EC Tools: An Overview / <i>Daniel Rivero, University of A Coruña, Spain; and Juan Ramón Rabuñal Dopico, University of A Coruña, Spain</i> | 125 |
| ANN-Based Defects' Diagnosis of Industrial Optical Devices / <i>Matthieu Voiry, University of Paris, France & SAGEM REOSC, France; Véronique Amarger, University of Paris, France; Joel Bernier, SAGEM REOSC, France; and Kurosh Madani, University of Paris, France</i> | 131 |
| Artificial Intelligence and Education / <i>Eduardo Sánchez, University of Santiago de Compostela, Spain; and Manuel Lama, University of Santiago de Compostela, Spain</i> | 138 |
| Artificial Intelligence and Rubble-Mound Breakwater Stability / <i>Gregorio Iglesias Rodriguez, University of Santiago de Compostela, Spain; Alberte Castro Ponte, University of Santiago de Compostela, Spain; Rodrigo Carballo Sanchez, University of Santiago de Compostela, Spain; and Miguel Ángel Losada Rodriguez, University of Granada, Spain</i> | 144 |
| Artificial Intelligence for Information Retrieval / <i>Thomas Mandl, University of Hildesheim, Germany</i> | 151 |
| Artificial Intelligence in Computer-Aided Diagnosis / <i>Paulo Eduardo Ambrósio, Santa Cruz State University, Brazil</i> | 157 |
| Artificial Neural Networks and Cognitive Modelling / <i>Amanda J.C. Sharkey, University of Sheffield, UK</i> .. | 161 |
| Artificial NeuroGlial Networks / <i>Ana Belén Porto Pazos, University of A Coruña, Spain; Alberto Alvarellos González, University of A Coruña, Spain; and Félix Montañés Pazos, University of A Coruña, Spain</i> | 167 |
| Association Rule Mining / <i>Vasudha Bhatnagar, University of Delhi, India; and Sarabjeet Kochhar, University of Delhi, India</i> | 172 |
| Automated Cryptanalysis / <i>Otokar Grošek, Slovak University of Technology, Slovakia; and Pavol Zajac, Slovak University of Technology, Slovakia</i> | 179 |

| | |
|--|-----|
| Automated Cryptanalysis of Classical Ciphers / <i>Otokar Grošek, Slovak University of Technology, Slovakia; and Pavol Zajac, Slovak University of Technology, Slovakia</i> | 186 |
| Automatic Classification of Impact-Echo Spectra I / <i>Addisson Salazar, iTEAM, Polytechnic University of Valencia, Spain; and Arturo Serrano, iTEAM, Polytechnic University of Valencia, Spain</i> | 192 |
| Automatic Classification of Impact-Echo Spectra II / <i>Addisson Salazar, iTEAM, Polytechnic University of Valencia, Spain; and Arturo Serrano, iTEAM, Polytechnic University of Valencia, Spain</i> | 199 |
| AVI of Surface Flaws on Manufactures I / <i>Girolamo Fornarelli, Politecnico di Bari, Italy; and Antonio Giaquinto, Politecnico di Bari, Italy</i> | 206 |
| AVI of Surface Flaws on Manufactures II / <i>Girolamo Fornarelli, Politecnico di Bari, Italy; and Antonio Giaquinto, Politecnico di Bari, Italy</i> | 211 |
| Basic Cellular Neural Networks Image Processing / <i>J. Álvaro Fernández, University of Extremadura, Badajoz, Spain</i> | 218 |
| Bayesian Neural Networks for Image Restoration / <i>Radu Mutihac, University of Bucharest, Romania</i> | 223 |
| Behaviour-Based Clustering of Neural Networks / <i>María José Castro-Bleda, Universidad Politécnica de Valencia, Spain; Salvador España-Boquera, Universidad Politécnica de Valencia, Spain; and Francisco Zamora-Martínez, Universidad Politécnica de Valencia, Spain</i> | 231 |
| Bio-Inspired Algorithms in Bioinformatics I / <i>José Antonio Seoane Fernández, University of A Coruña, Spain; and Mónica Miguélez Rico, University of A Coruña, Spain</i> | 236 |
| Bio-Inspired Algorithms in Bioinformatics II / <i>José Antonio Seoane Fernández, University of A Coruña, Spain; and Mónica Miguélez Rico, University of A Coruña, Spain</i> | 241 |
| Bioinspired Associative Memories / <i>Roberto A. Vazquez, Center for Computing Research, IPN, Mexico; and Humberto Sossa, Center for Computing Research, IPN, Mexico</i> | 248 |
| Bio-Inspired Dynamical Tools for Analyzing Cognition / <i>Manuel G. Bedia, University of Zaragoza, Spain; Juan M. Corchado, University of Salamanca, Spain; and Luis F. Castillo, National University, Colombia</i> | 256 |
| Biometric Security Technology / <i>Marcos Faundez-Zanuy, Escola Universitària Politècnica de Mataró, Spain</i> | 262 |
| Blind Source Separation by ICA / <i>Miguel A. Ferrer, University of Las Palmas de Gran Canaria, Spain; and Aday Tejera Santana, University of Las Palmas de Gran Canaria, Spain</i> | 270 |
| Chaotic Neural Networks / <i>Emilio Del-Moral-Hernandez, University of São Paulo, Brazil</i> | 275 |
| Class Prediction in Test Sets with Shifted Distributions / <i>Óscar Pérez, Universidad Autónoma de Madrid, Spain; and Manuel Sánchez-Montañés, Universidad Autónoma de Madrid, Spain</i> | 282 |

| | |
|--|-----|
| Cluster Analysis of Gene Expression Data / <i>Alan Wee-Chung Liew, Griffith University, Australia; Ngai-Fong Law, The Hong Kong Polytechnic University, Hong Kong; and Hong Yan, City University of Hong Kong, Hong Kong & University of Sydney, Australia</i> | 289 |
| Clustering Algorithm for Arbitrary Data Sets / <i>Yu-Chen Song, Inner Mongolia University of Science and Technology, China; and Hai-Dong Meng, Inner Mongolia University of Science and Technology, China</i> | 297 |
| CNS Tumor Prediction Using Gene Expression Data Part I / <i>Atiq Islam, University of Memphis, USA; Khan M. Iftikharuddin, University of Memphis, USA; E. Olusegun George, University of Memphis, USA; and David J. Russomanno, University of Memphis, USA</i> | 304 |
| CNS Tumor Prediction Using Gene Expression Data Part II / <i>Atiq Islam, University of Memphis, USA; Khan M. Iftikharuddin, University of Memphis, USA; E. Olusegun George, University of Memphis, USA; and David J. Russomanno, University of Memphis, USA</i> | 312 |
| Combining Classifiers and Learning Mixture-of-Experts / <i>Lei Xu, Chinese University of Hong Kong, Hong Kong & Peking University, China; and Shun-ichi Amari, Brain Science Institute, Japan</i> | 318 |
| Commonsense Knowledge Representation I / <i>Phillip Ein-Dor, Tel-Aviv University, Israel</i> | 327 |
| Commonsense Knowledge Representation II / <i>Phillip Ein-Dor, Tel-Aviv University, Israel</i> | 334 |
| Comparative Study on E-Note-Taking, A / <i>Shaista Rashid, University of Bradford, UK; and Dimitris Rigas, University of Bradford, UK</i> | 337 |
| Comparison of Cooling Schedules for Simulated Annealing, A / <i>José Fernando Díaz Martín, University of Deusto, Spain; and Jesús M. Riaño Sierra, University of Deusto, Spain</i> | 344 |
| Complex Systems Modeling by Cellular Automata / <i>Jiří Kroc, Section Computational Science, The University of Amsterdam, The Netherlands; and Peter M.A. Sloot, Section Computational Science, The University of Amsterdam, The Netherlands</i> | 353 |
| Complex-Valued Neural Networks / <i>Tohru Nitta, AIST, Japan</i> | 361 |
| Component Analysis in Artificial Vision / <i>Oscar Déniz Suárez, University of Las Palmas de Gran Canaria, Spain; and Gloria Bueno García, University of Castilla-La Mancha, Spain</i> | 367 |
| Computational Methods in Biomedical Imaging / <i>Michele Piana, Università' di Verona, Italy</i> | 372 |
| Computer Morphogenesis in Self-Organizing Structures / <i>Enrique Fernández-Blanco, University of A Coruña, Spain; and Julián Dorado, University of A Coruña, Spain</i> | 377 |
| Computer Vision for Wave Flume Experiments / <i>Óscar Ibáñez, University of A Coruña, Spain; and Juan Rabuñal Dopico, University of A Coruña, Spain</i> | 383 |
| Conditional Hazard Estimating Neural Networks / <i>Antonio Eleuteri, Royal Liverpool University Hospital, UK; Azzam Taktak, Royal Liverpool University Hospital, UK; Bertil Damato, Royal Liverpool University Hospital, UK; Angela Douglas, Liverpool Women's Hospital, UK; and Sarah Coupland, Royal Liverpool University Hospital, UK</i> | 390 |

| | |
|---|-----|
| Configuration / <i>Luca Anselma, Università di Torino, Italy; and Diego Magro, Università di Torino, Italy</i> | 396 |
| Constraint Processing / <i>Roman Barták, Charles University in Prague, Czech Republic</i> | 404 |
| Continuous ACO in a SVR Traffic Forecasting Model / <i>Wei-Chiang Hong, Oriental Institute of Technology, Taiwan</i> | 410 |
| Data Mining Fundamental Concepts and Critical Issues / <i>John Wang, Montclair State University, USA; Qiyang Chen, Montclair State University, USA; and James Yao, Montclair State University, USA</i> | 418 |
| Data Warehousing Development and Design Methodologies / <i>James Yao, Montclair State University, USA; and John Wang, Montclair State University, USA</i> | 424 |
| Decision Making in Intelligent Agents / <i>Mats Danielson, Stockholm University, Sweden & Royal Institute of Technology, Sweden; and Love Ekenberg, Stockholm University, Sweden & Royal Institute of Technology, Sweden</i> | 431 |
| Decision Tree Applications for Data Modelling / <i>Man Wai Lee, Brunel University, UK; Kyriacos Chrysostomou, Brunel University, UK; Sherry Y. Chen, Brunel University, UK; and Xiaohui Liu, Brunel University, UK</i> | 437 |

Preface

Through the history the man has always hoped the boost of three main characteristics: physical, metaphysical and intellectual.

From the physical viewpoint he invented and developed all kind of tools: levers, wheels, cams, pistons, etc., until achieving the sophisticated machines existing nowadays.

Regarding the metaphysical aspect, the initial celebration of magical-animistic rituals led to attempts, either real or literary, for creating *ex nihilo* life: life from inert substance. The most actual approaches involve the cryoconservation of deceased people for them to be returned to life in the future; the generation of life at the laboratories by means of cells, tissues, organs, systems or individuals created from previously frozen stem cells is also currently aimed.

The third aspect considered, the intellectual one, is the most interesting here. There have been multiple contributions, since devices that increased the calculi ability as the abacus appeared, until the later theoretical proposals for trying to solve problems, as the *Ars Magna* by Ramón Lull. The first written reference of the Artificial Intelligence that is known is *The Iliad*, where Homer describes the visit of the goddess Thetis and her son Achilles to the workshop of Hephaestus, god of smiths: At once he was helped along by female servants made of gold, who moved to him. They look like living servant girls, possessing minds, hearts with intelligence, vocal chords, and strength.

However, the first reference of Artificial Intelligence, as it is currently understood, can be found in the proposal made by J. McCarthy to the Rockefeller Foundation in 1956; this proposal hoped for funds that might support a month-lasting meeting of twelve researchers of the Dartmouth Summer Research Project in order to establish the basis of the, McCarthy-named, Artificial Intelligence.

Although the precursors of the Artificial Intelligence (S. Ramón y Cajal, N. Wiener, D. Hebb, C. Shannon and J. McCulloch, among many others), come from multiple science disciplines, the true driving forces (A. Turing, J. von Neumann, M. Minsky, T. Gödel, ...) emerge in the second third of the XX century with the apparition of certain tools, the computers, capable of handling fairly complex problems. Some other scientists, as J. Hopfield or J. Holland, proposed at the last third of the century some biology-inspired approaches that enabled the treatment of complex problems of the real world that even might require certain adaptive ability.

All this long and productive trend of the history of the Artificial Intelligence demanded an encyclopaedia that might give expression to the current situation of this multidisciplinary topic, where researches from multiple fields as neuroscience, computing science, cognitive sciences, exact sciences and different engineering areas converge.

This work intends to provide a wide and well balanced coverage of all the points of interest that currently exist in the field of Artificial Intelligence, from the most theoretical fundamentals to the most recent industrial applications.

Multiple researches have been contacted and several notifications have been performed in different forums of the scientific field dealt here.

All the proposals have been carefully revised by the editors for balancing, as far as possible, the contributions, with the intention of achieving an accurately wide document that might exemplify this field.

A first selection was performed after the reception of all the proposals and it was later sent to three external expert reviewers in order to carry out a double-blind revision based on a peer review. As a result of this strict and complex process, and before the final acceptance, a high number of contributions (80% approximately) were rejected or required to be modified.

The effort of the last two years is now believed to be worthwhile; at least this is the belief of the editors who, with the invaluable help of a high number of people mentioned in the acknowledgements, have managed to get this complete encyclopaedia off the ground. The numbers speak for themselves: 233 articles published that have been carried out by 442 authors from 38 different countries and also revised by 238 scientific reviewers. The diverse and comprehensive coverage of the disciplines directly related with the Artificial Intelligence is also believed to contribute to a better understanding of all the researching related to this important field of study. It was also intended that the contributions compiled in this work might have a considerable impact on the expansion and the development of the body of knowledge related to this wide field, for it to be an important reference source used by researchers and system developers of this area. It was hoped that the encyclopaedia might be an effective help in order to achieve a better understanding of concepts, problems, trends, challenges and opportunities related to this field of study; it should be useful for the research colleagues, for the teaching personnel, for the students, etc. The editors will be happy to know that this work could inspire the readers for contributing to new advances and discoveries in this fantastic work area that might themselves also contribute to a better life quality of different society aspects: productive processes, health care or any other area where a system or product developed by techniques and procedures of Artificial Intelligence might be used.

About the Editors

Juan Ramón Rabuñal Dopico is associate professor in the Department of Information and Communications Technologies, University of A Coruña (Spain). He finished his graduate in computer science in 1996, and in 2002, he became a PhD in computer science with his thesis “Methodology for the Development of Knowledge Extraction Systems in ANNs” and he became a PhD in civil engineering in 2008. He has worked on several Spanish and European projects and has published many books and papers in several international journals. He is currently working in the areas of evolutionary computation, artificial neural networks, and knowledge extraction systems.

Julian Dorado is associate professor in the Faculty of Computer Science, University of A Coruña (Spain). He finished his graduate in computer science in 1994. In 1999, he became a PhD, with a special mention of European doctor. In 2004, he finished his graduate in biology. He has worked as a teacher of the university for more than 8 years. He has published many books and papers in several journals and international conferences. He is presently working on bioinformatics, evolutionary computing, artificial neural networks, computer graphics, and data mining.

Alejandro Pazos is professor in computer science, University of A Coruña (Spain). He was born in Padron in 1959. He is MD by Faculty of Medicine, University of Santiago de Compostela in 1987. He obtained a Master of Knowledge Engineering in 1989 and a PhD in computer science in 1990 from the Polytechnique University of Madrid. He also archives the PhD grade in Medicine in 1996 by the University Complutense of Madrid. He has worked with research groups at Georgia Institute of Technology, Harvard Medical School, Stanford University, Politechnique University of Madrid, etc. He funded and is the director of the research laboratory Artificial Neural Networks and Adaptative Systems in Computer science Faculty and is co-director of the Medical Informatics and Radiology Diagnostic Center at the University of A Coruña.

Active Learning with SVM

INTRODUCTION

With the increasing demand of multimedia information retrieval, such as image and video retrieval from the Web, there is a need to find ways to train a classifier when the training dataset is combined with a small number of labelled data and a large number of unlabeled one. Traditional supervised or unsupervised learning methods are not suited to solving such problems particularly when the problem is associated with data in a high-dimension space. In recent years, many methods have been proposed that can be broadly divided into two groups: **semi-supervised** and **active learning** (AL). Support Vector Machine (SVM) has been recognized as an efficient tool to deal with high-dimensionality problems, a number of researchers have proposed algorithms of Active Learning with SVM (ALSVM) since the turn of the Century. Considering their rapid development, we review, in this chapter, the state-of-the-art of ALSVM for solving classification problems.

BACKGROUND

The general framework of AL can be described as in Figure 1. It can be seen clearly that its name – **active learning** – comes from the fact that the learner can improve the classifier by actively choosing the “optimal” data from the potential query set Q and adding it into the current labeled training set L after getting its label during the processes. The key point of AL is its sample selection criteria.

AL in the past was mainly used together with neural network algorithm and other learning algorithms. Statistical AL is one classical method, in which the sample minimizing either the variance (D. A. Cohn, Ghahramani, & Jordan, 1996), bias (D. A. Cohn, 1997) or generalisation error (Roy & McCallum, 2001) is queried to the oracle. Although these methods have

strong theoretical foundation, there are two common problems limiting their application: one is how to estimate the posterior distribution of the samples, and the other is its prohibitively high computation cost. To deal with the above two problems, a series of **version space based AL** methods, which are based on the assumption that the target function can be perfectly expressed by one hypothesis in the version space and in which the sample that can reduce the volume of the version space is chosen, have been proposed. Examples are query by committee (Freund, Seung, Shamir, & Tishby, 1997), and SG AL (D. Cohn, Atlas, & Ladner, 1994). However the complexity of version space made them intractable until the version space based ALSVMs have emerged.

The success of SVM in the 90s has prompted researchers to combine AL with SVM to deal with the semi-supervised learning problems, such as distance-based (Tong & Koller, 2001), RETIN (Gosselin & Cord, 2004) and Multi-view (Cheng & Wang, 2007) based ALSVMs. In the following sections, we summarize existing well-known ALSVMs under the framework of **version space theory**, and then briefly describe some mixed strategies. Lastly, we will discuss the research trends for ALSVM and give conclusions for the chapter.

VERSION SPACE BASED ACTIVE LEARNING WITH SVM

The idea of almost all existing heuristic ALSVMs is explicitly or implicitly to find the sample which can reduce the volume of the **version space**. In this section, we first introduce their theoretical foundation and then review some typical ALSVMs.

Figure 1. Framework of active learning

| ➤ | H : the hypothesis space |

Version Space Theory

Based on the Probability Approximation Correct learning model, the goal of machine learning is to find a consistent classifier which has the lowest generalization error bound. The Gibbs generalization error bound (McAllester, 1998) is defined as

$$\varepsilon_{Gibbs}(m, P_H, z, \delta) = \frac{1}{m} \left(\ln \left(\frac{1}{P_H(V(z))} \right) \right) + \ln \left(\frac{em^2}{\delta} \right)$$

where P_H denotes a prior distribution over hypothesis space H , $V(z)$ denotes the version space of the training set z , m is the number of z and δ is a constant in $[0, 1]$. It follows that the generalization error bound of the consistent classifiers is controlled by the volume of the version space if the distribution of the version space is uniform. This provides a theoretical justification for version space based ALSVMs.

Query by Committee with SVM

This algorithm was proposed by (Freund et al., 1997) in which $2k$ classifiers were randomly sampled and the sample on which these classifiers have maximal disagreement can approximately halve the **version space** and then will be queried to the oracle. However, the complexity of the structure of the version space leads to the difficulty of random sampling within it.

(Warmuth, Ratsch, Mathieson, Liao, & Lemmem, 2003) successfully applied the algorithm of playing billiard to randomly sample the classifiers in the SVM version space and the experiments showed that its performance was comparable to the performance of **standard distance-based ALSVM** (SD-ALSVM) which will be introduced later. The deficiency is that the processes are time-consuming.

Standard Distance Based Active Learning with SVM

For SVM, the **version space** can be defined as:

$$V = \{w \in W \mid \|w\| = 1, y_i(w \bullet \Phi(x_i)) > 0, i = 1, \dots, m\}$$

where $\Phi(\cdot)$ denotes the function which map the original input space X into a high-dimensional space $\Phi(X)$, and W denotes the parameter space. SVM has two properties which lead to its tractability with AL. The first is its duality property that each point w in V corresponds to one hyperplane in $\Phi(X)$ which divides $\Phi(X)$ into two parts and vice versa. The other property is that the solution of SVM w^* is the center of the **version space** when the version space is symmetric or near to its center when it is asymmetric.

Based on the above two properties, (Tong & Koller, 2001) inferred a lemma that the sample nearest to the

Figure 2. Illustration of standard distance-based ALSVM

A

Figure 2a. The projection of the parameter space around the Version Space

Figure 2b. In the induced feature space

decision boundary can make the expected size of the version space decrease fastest. Thus the sample nearest to the decision boundary will be queried to the oracle (Figure 2). This is the so-called SD-ALSVM which has low additional computations for selecting the queried sample and fine performance in real applications.

Batch Running Mode Distance Based Active Learning with SVM

When utilizing batch query, (Tong & Koller, 2001) simply selected multiple samples which are nearest to the decision boundary. However, adding a batch of such samples cannot ensure the largest reduction of the size of version space, such as an example shown in figure 3. Although every sample can nearly halve the version space, three samples together can still reduce about 1/2,

instead of 7/8, of the size of the version space. It can be observed that this was ascribed to the small angles between their induced hyperplanes.

To overcome this problem, (Brinker, 2003) proposed a new selection strategy by incorporating **diversity** measure that considers the angles between the induced hyperplanes. Let the labeled set be L and the pool query set be Q in the current round, then based on the diversity criterion the further added sample x_q should be

$$x_q = \min_{x_j \in Q} \max_{x_i \in L} \frac{|k(x_j, x_i)|}{\sqrt{k(x_j, x_j)k(x_i, x_i)}}$$

Figure 3. One example of simple batch querying with “a”, “b” and “c” samples with pure SD-ALSVM

Figure 4. One example of batch querying with “a”, “b” and “c” samples by incorporating diversity into SD-ALSVM

where $\angle(x_j, x_i)$ denotes the cosine value of the angle between two hyperplanes induced by x_j and x_i , thus it is known as angle diversity criterion. It can be observed that the reduced volume of the version space in figure 4 is larger than that in Figure 3.

RETIN Active Learning

Let $(I_j)_{j \in [1 \dots n]}$ be the samples in a potential query set Q , and $r(i, k)$ be the function that, at iteration i , codes the position k in the relevance ranking according to the distance to the current decision boundary, then a sequence can be obtained as follows:

$$\underbrace{I_{r(i,1)}, I_{r(i,2)}, \dots, I_{r(i,s(i))}}_{\text{most relevant}}, \underbrace{I_{r(i,s(i)+1)}, \dots, I_{r(i,s(i)+m-1)}}_{\text{queried data}}, \underbrace{I_{r(i,n)}}_{\text{least relevant}}$$

In SD-ALSVM, $s(i)$ is such as $I_{r(i,s(i))}, \dots, I_{r(i,s(i)+m-1)}$ are the m closest samples to the SVM boundary. This strategy implicitly relies on a strong assumption: an accurate estimation of SVM boundary. However, the decision boundary is usually unstable at the initial iterations. (Gosselin & Cord, 2004) noticed that, even if the decision boundary may change a lot during the earlier iterations, the ranking function $r()$ is quite stable. Thus they proposed a balanced selection criterion that

is independent on the frontier and in which an adaptive method was designed to tune s during the feedback iterations. It was expressed by

$$s(i+1) = s(i) + h(r_{rel}(i) - r_{irr}(i))$$

where $h(x, y) = k \times (x - y)$ which characterizes the system dynamics (k is a positive constant), $r_{rel}(i)$ and $r_{irr}(i)$ denote the number of relevant and irrelevant samples in the queried set in the i th iteration. This way, the number of relevant and irrelevant samples in the queried set will be roughly equal.

Mean Version Space Criterion

(He, Li, Zhang, Tong, & Zhang, 2004) proposed a selection criterion by minimizing the **mean version space** which is defined as

$$C_{MVS}(x_k) = Vol(V_i^+(x_k)) P(y_k = 1 | x_k) + Vol(V_i^-(x_k)) P(y_k = -1 | x_k)$$

where $Vol(V_i^+(x_k))$ ($Vol(V_i^-(x_k))$) denotes the volume of the version space after adding an unlabelled sample x_k into the i th round training set. The mean version space includes both the volume of the version space and the posterior probabilities. Thus they considered that the criterion is better than the SD-ALSVM. However, the computation of this method is time-consuming.

Multi-View Based Active Learning

Different from the algorithms which are based only on one whole feature set, **multi-view** methods are based on multiple sub-feature ones. Several classifiers are first trained on different sub-feature sets. Then the samples on which the classifiers have the largest disagreements comprise the contention set from which queried samples are selected. first (I. Muslea, Minton, & Knoblock, 2000) applied in AL and (Cheng & Wang, 2007) implemented it with ALSVM to produce a Co-SVM algorithm which was reported to have better performance than the SD-ALSVM.

Multiple classifiers can find the rare samples because they observe the samples with different views. Such property is very useful to find the diverse parts belonging to the same category. However, multi-view based methods demand that the relevant classifier can classify the samples well and that all feature sets are

uncorrelated. It is difficult to ensure this condition in real applications.

MIXED ACTIVE LEARNING

Instead of single AL strategies in the former sections, we will discuss two mixed AL modes in this section: one is combining different selection criteria and another is incorporating **semi-supervised learning** into AL.

Hybrid Active Learning

Contrast to developing a new AL algorithm that works well for all situations, some researchers argued that combining different methods, which are usually complementary, is a better way, for each method has its advantages and disadvantages. The intuitive structure of the hybrid strategy is parallel mode. The key point here is how to set the weights of different AL methods.

The simplest way is to set fixed weights according to experience and it was used by most existing methods. The Most Relevant/Irrelevant (L. Zhang, Lin, & Zhang, 2001) strategies can help to stabilize the decision boundary, but have low learning rates; while standard distance-based methods have high learning rates, but have unstable frontiers at the initial feedbacks. Considering this, (Xu, Xu, Yu, & Tresp, 2003) combined these two strategies to achieve better performance than only using a single strategy. As stated before, the **diversity** and distance-based strategies are also complementary and (Brinker, 2003), (Ferecatu, Crucianu, & Boujemaa, 2004) and (Dagli, Rajaram, & Huang, 2006) combined angle, inner product and entropy **diversity** strategy with standard distance-based one respectively.

However, the strategy of the fixed weights can not fit well into all datasets and all learning iterations. So the weights should be set dynamically. In (Baram, El-Yaniv, & Luz, 2004), all the weights were initialized with the same value, and were modified in the later iterations by using EXP4 algorithm. In this way, the resulting AL algorithm is empirically shown to consistently perform almost as well as and sometimes outperform the best algorithm in the ensemble.

Semi-Supervised Active Learning

1. Active Learning with Transductive SVM

In the first stages of SD-ALSVM, a few labeled data may lead to great deviation of the current solution from the true solution; while if unlabeled samples are considered, the solution may be closer to the true solution. (Wang, Chan, & Zhang, 2003) showed that the closer the current solution is to the true one, the larger the size of the version space will be reduced. They incorporated Transductive SVM (TSVM) to produce more accurate intermediate solutions. However, several studies (T. Zhang & Oles, 2000) challenged that TSVM might not be so helpful from unlabeled data in theory and in practice. (Hoi & Lyu, 2005) applied the semi-supervised learning techniques based on the Gaussian fields and Harmonic functions instead and the improvements were reported to be significant.

2. Incorporating EM into Active Learning

(McCallum & Nigam, 1998) combined Expectation Maximization (EM) with the strategy of querying by committee. And (Ion Muslea, Minton, & Knoblock, 2002) integrated Multi-view AL algorithm with EM to get the Co-EMT algorithm which can work well in the situation where the views are incompatible and correlated.

FUTURE TRENDS

How to Start the Active Learning

AL can be regarded as the problem of searching target function in the version space, so a good initial classifier is important. When the objective category is diverse, the initial classifier becomes more important, for bad one may result in converging to a local optimal solution, i.e., some parts of the objective category may not be correctly covered by the final classifier. Two-stage (Cord, Gosselin, & Philipp-Foliguet, 2007), long-term learning (Yin, Bhanu, Chang, & Dong, 2005), and pre-cluster (Engelbrecht & BRITS, 2002) strategies are promising.

Feature-Based Active Learning

In AL, the feedback from the oracle can also help to identify the important features, and (Raghavan, Madani, & Jones, 2006) showed that such works can improve the performance of the final classifier significantly. In (Su, Li, & Zhang, 2001), Principal Components Analysis was used to identify important features. To our knowledge, there are few reports addressing the issue.

The Scaling of Active Learning

The scaling of AL to very large database has not been extensively studied yet. However, it is an important issue for many real applications. Some approaches have been proposed on how to index database (Lai, Goh, & Chang, 2004) and how to overcome the concept complexities accompanied with the scalability of the dataset (Panda, Goh, & Chang, 2006).

CONCLUSION

In this chapter, we summarize the techniques of ALSVM which have been an area of active research since 2000. We first focus on the descriptions of heuristic ALSVM approaches within the framework of the theory of version space minimization. Then mixed methods which can complement the deficiencies of single ones are introduced and finally future research trends focus on techniques for selecting the initial labeled training set, feature-based AL and the scaling of AL to very large database.

KEY TERMS

Heuristic Active Learning: The set of active learning algorithms in which the sample selection criteria is based on some heuristic objective function. For example, version space based active learning is to select the sample which can reduce the size of the version space.

Hypothesis Space: The set of all hypotheses in which the objective hypothesis is assumed to be found.

Semi-Supervised Learning: The set of learning algorithms in which both labelled and unlabelled data in the training dataset are directly used to train the classifier.

Statistical Active Learning: The set of active learning algorithms in which the sample selection criteria is based on some statistical objective function, such as minimization of generalisation error, bias and variance. Statistical active learning is usually statistically optimal.

Supervised Learning: The set of learning algorithms in which the samples in the training dataset are all labelled.

Unsupervised Learning: The set of learning algorithms in which the samples in training dataset are all unlabelled.

Version Space: The subset of the hypothesis space which is consistent with the training set.

Adaptive Algorithms for Intelligent Geometric Computing

A

M. L. Gavrilova

University of Calgary, Canada

INTRODUCTION

This chapter spans topics from such important areas as Artificial Intelligence, Computational Geometry and Biometric Technologies. The primary focus is on the proposed *Adaptive Computation Paradigm* and its applications to surface modeling and biometric processing.

Availability of much more affordable storage and high resolution image capturing devices have contributed significantly over the past few years to accumulating very large datasets of collected data (such as GIS maps, biometric samples, videos etc.). On the other hand, it also created significant challenges driven by the higher than ever volumes and the complexity of the data, that can no longer be resolved through acquisition of more memory, faster processors or optimization of existing algorithms. These developments justified the need for radically new concepts for massive data storage, processing and visualization. To address this need, the current chapter presents the original methodology based on the paradigm of the *Adaptive Geometric Computing*. The methodology enables storing complex data in a compact form, providing efficient access to it, preserving high level of details and visualizing dynamic changes in a smooth and continuous manner.

The first part of the chapter discusses adaptive algorithms in real-time visualization, specifically in GIS (Geographic Information Systems) applications. Data structures such as Real-time Optimally Adaptive Mesh (ROAM) and Progressive Mesh (PM) are briefly surveyed. The adaptive method *Adaptive Spatial Memory (ASM)*, developed by R. Apu and M. Gavrilova, is then introduced. This method allows fast and efficient visualization of complex data sets representing terrains, landscapes and Digital Elevation Models (DEM). Its advantages are briefly discussed.

The second part of the chapter presents application of adaptive computation paradigm and evolutionary computing to missile simulation. As a result, patterns of complex behavior can be developed and analyzed.

The final part of the chapter marries a concept of *adaptive computation* and *topology-based techniques* and discusses their application to challenging area of *biometric computing*.

BACKGROUND

For a long time, researchers were pressed with questions on how to model real-world objects (such as terrain, facial structure or particle system) realistically, while at the same time preserving rendering efficiency and space. As a solution, grid, mesh, TIN, Delaunay triangulation-based and other methods for model representation were developed over the last two decades. Most of these are static methods, not suitable for rendering dynamic scenes or preserving higher level of details.

In 1997, first methods for dynamic model representation: Real-time Optimally Adapting Mesh (*ROAM*) (Duchaineau et. al., 1997, Lindstrom and Koller, 1996) and Progressive Mesh (PM) (Hoppe, 1997) were developed. Various methods have been proposed to reduce a fine mesh into an optimized representation so that the optimized mesh contains less primitives and yields maximum detail. However, this approach had two major limitations. Firstly, the cost of optimization is very expensive (several minutes to optimize one medium sized mesh). Secondly, the generated non-uniform mesh is still static. As a result, it yields poor quality when only a small part of the mesh is being observed. Thus, even with the further improvements, these methods were not capable of dealing with large amount of complex data or significantly varied level of details. They have soon were replaced by a different computational model for rendering geometric meshes (Li Sheng et. al. 2003, Shafae and Pajarola, 2003). The model employs a continuous refinement criteria based on an error metric to optimally adapt to a more accurate representation. Therefore, given a mesh representation and a small change in the viewpoint, the optimized mesh

for the next viewpoint can be computed by refining the existing mesh.

ADAPTIVE GEOMETRIC COMPUTING

This chapter presents *Adaptive Multi-Resolution Technique* for real-time terrain visualization utilizing a clever way of optimizing mesh dynamically for smooth and continuous visualization with a very high efficiency (frame rate) (Apu and Gavrilova (2005) (2007)). Our method is characterized by the efficient representation of massive underlying terrain, utilizes efficient transition between detail levels, and achieves frame rate constancy ensuring visual continuity. At the core of the method is *adaptive processing*: a formalized hierarchical representation that exploits the *subsequent refinement* principal. This allows us a full control over the complexity of the feature space. An error metric is assigned by a higher level process where objects (or features) are initially classified into different labels. Thus, this adaptive method is highly useful for feature space representation. In 2006, Gavrilova and Apu showed that such methods can act as a powerful tool not only for terrain rendering, but also for motion planning and adaptive simulations (Apu and Gavrilova, 2006). They introduced *Adaptive Spatial Memory (ASM)* model that utilizes adaptive approach for real-time online algorithm for multi-agent collaborative motion planning. They have demonstrate that the powerful notion of adaptive computation can be applied to perception and understanding of space. Extension of this method for 3D motion planning as part of collaborative research with Prof. I. Kolingerova group has been reported to be

significantly more efficient than conventional methods (Broz et.al., 2007).

We first move to discuss *evolutionary computing*. We demonstrate the power of adaptive computation by developing and applying adaptive computational model to missile simulation (Apu and Gavrilova, 2006). The developed adaptive algorithms described above have a property that spatial memory units can form, refine and collapse to simulate learning, adapting and responding to stimuli. The result is a complex multi-agent learning algorithm that clearly demonstrates organic behaviors such as sense of territory, trails, tracks etc. observed in flocks/herds of wild animals and insects. This gives a motivation to explore the mechanism in application to swarm behavior modeling.

Swarm Intelligence (SI) is the property of a system whereby the collective behaviors of unsophisticated agents interacting locally with their environment cause coherent functional global patterns to emerge (Bonabeau, 1999). Swarm intelligence provides a basis for exploration of a collective (distributed) behavior of a group of agents without centralized control or the provision of a global model. Agents in such system have limited perception (or intelligence) and cannot individually carry out the complex tasks. According to Bonebeau, by regulating the behavior of the agents in the swarm, one can demonstrate emergent behavior and intelligence as a collective phenomenon. Although the swarming phenomenon is largely observed in biological organisms such as an ant colony or a flock of birds, it is recently being used to simulate complex dynamic systems focused towards accomplishing a well-defined objective (Kennedy, 2001, Raupp and Thalmann, 2001).

Figure 1. Split and merge operations in ASM model

Let us now investigate application of the adaptive computational paradigm and swarm intelligence concept to missile behavior simulation (Apu and Gavrilova, 2006). First of all, let us note that complex strategic behavior can be observed by means of a task oriented artificial evolutionary process in which behaviors of individual missiles are described in surprising simplicity. Secondly, the global effectiveness and behavior of the missile swarm is relatively unaffected by disruption or destruction of individual units. From a strategic point of view, this adaptive behavior is a strongly desired property in military applications, which motivates our interest in applying it to missile simulation. Note that this problem was chosen as it presents a complex challenge for which an optimum solution is very hard to obtain using traditional methods. The dynamic and competitive relationship between missiles and turrets makes it extremely difficult to model using a deterministic approach. It should also be noted that the problem has an easy evaluation metric that allows determining fitness values precisely.

Now, let us summarize the idea of evolutionary optimization by applying genetic algorithm to evolve the missile genotype. We are particularly interested in observing the evolution of complex 3D formations and tactical strategies that the swarm learns to maximize their effectiveness during an attack simulation run. The simulation is based on attack, evasion and defense. While the missile sets strategy to strike the target, the battle ship prepares to shoot down as many missiles as possible (Figure 2 illustrates the basic missile ma-

neuvers). Each attempt to destroy the target is called an attack simulation run. Its effectiveness equals to the number of missiles hitting the target. Therefore the outcome of the simulation is easily quantifiable. On the other hand, the interaction between missiles and the battleship is complex and nontrivial. As a result, war strategies may emerge in which a local penalty (i.e. sacrificing a missile) can optimize global efficiency (i.e. deception strategy). The simplest form of information known to each missile is its position and orientation and the location of the target. This information is augmented with information about missile neighborhood and environment, which influences missile navigation pattern. For actual missile behavior simulation, we use strategy based on the modified version of Boids flocking technique.

We have just outlined the necessary set of actions to reach the target or interact with the environment. This is the basic building block of missile navigation. The gene string is another important part that reflects the complexity with which such courses of action could be chosen. It contains a unique combination of maneuvers (such as attack, evasion, etc.) that evolve to create complex combined intelligence. We describe the fitness of the missile gene in terms of collective performance. After investigating various possibilities, we developed and used a two dimensional adaptive fitness function to evolve the missile strains in one evolutionary system. Details on this approach can be found in (Apu and Gavrilova, 2006).

After extensive experimentation, we have found many interesting characteristics, such as geometric attack formation and organic behaviors observed among swarms in addition to the highly anticipated strategies such as simultaneous attack, deception, retreat and other strategies (see Figure 3). We also examined the adaptability by randomizing the simulation coordinates, distance, initial formation, attack rate, and other parameters of missiles and measured the mean and variance of the fitness function. Results have shown that many of the genotypes that evolved are *highly adaptive* to the environment.

We have just reviewed the application of the adaptive computational paradigm to swarm intelligence and briefly described the efficient tactical swarm simulation method (Apu and Gavrilova 2006). The results clearly demonstrate that the swarm is able to develop complex strategy through the evolutionary process of genotype mutation. This contribution among other works on

Figure 2. Basic maneuvers for a missile using the Gene String

adaptive computational intelligence will be profiled in detail in the upcoming book as part of Springer-Verlag book series on Computational Intelligence (Gavrilova, 2007).

As stated in the introduction, adaptive computation is based on a variable complexity level of detail paradigm, where a physical phenomenon can be simulated by the continuous process of local adaptation of spatial complexity. As presented by M. Gavrilova in Plenary Lecture at 31A Eurographics Conference, France in 2006, the **adaptive paradigm** is a powerful computational model that can also be applied to vast area of biometric research. This section therefore reviews methods and techniques based on adaptive geometric methods in application to biometric problems. It emphasizes advantages that intelligent approach to geometric computing brings to the area of complex **biometric data processing** (Gavrilova 2007).

In information technology, **biometrics** refers to a study of physical and behavioral characteristics with the purpose of person identification (Yanushkevich, Gavrilova, Wang and Srihari, 2007). In recent years, the area of biometrics has witnessed a tremendous growth, partly as a result of a pressing need for increased security, and partly as a response to the new technological advances that are literally changing the way we live. Availability of much more affordable storage and the high resolution image biometric capturing devices have contributed to accumulating very large datasets of biometric data. In the earlier sections, we have studied the background of the adaptive mesh generation. Let us now look at the background research in topology-based data structures, and its application to biometric research. This information is highly relevant to goals of modeling and visualizing complex biometric data. At

the same time as adaptive methodology was developing in GIS, interest to **topology-based** data structures, such as **Voronoi diagrams** and **Delaunay triangulations**, has grown significantly. Some preliminary results on utilization of these topology-based data structures in biometric began to appear. For instance, research on image processing using Voronoi diagrams was presented in (Liang and Asano, 2004, Asano, 2006), studies of utilizing Voronoi diagram for fingerprint synthesis were conducted by (Bebis et. al., 1999, Capelli et. al. 2002), and various surveys of methods for modeling of human faces using triangular mesh appeared in (Wen and Huang, 2004, Li and Jain, 2005, Wayman et. al. 2005). Some interesting results were recently obtained in the BTLab, University of Calgary, through the development of topology-based feature extraction algorithms for fingerprint matching (Wang et. al. 2006, 2007, illustration is found in Figure 4), 3D facial expression modeling (Luo et. al. 2006) and iris synthesis (Wecker et. al. 2005). A comprehensive review of topology-based approaches in biometric modeling and synthesis can be found in recent book chapter on the subject (Gavrilova, 2007).

In this chapter, we propose to manage the challenges arising from large volumes of complex biometric data through the innovative utilization of the adaptive paradigm. We suggest combination of topology-based and hierarchy based methodology to store and search for biometric data, as well as to optimize such representation based on the data access and usage. Namely, retrieval of the data, or creating real-time visualization can be based on the dynamic pattern of data usage (how often, what type of data, how much details, etc.), recorded and analyzed in the process of the biometric system being used for recognition and identification purposes.

Figure 3. Complex formation and attack patterns evolved

Figure 4. Delaunay triangulation based technique for fingerprint matching

In addition to using this information for optimized data representation and retrieval, we also propose to incorporate intelligent learning techniques to predict most likely patterns of the system usage and to represent and organize data accordingly.

On a practical side, to achieve our goal, we propose a novel way to represent complex biometric data through the organization of the data in a hierarchical tree-like structure. Such organization is similar in principle to the Adaptive Memory Subdivision (AMS), capable of representing and retrieving various amounts of information and level of detail that needs to be represented. Spatial quad-tree is used to hold the information about the system, as well as the instructions on how to process this information. Expansion is realized through the spatial subdivision technique that refines the data and increases level of details, and the collapsing is realized through the merge operation that simplifies the data representation and makes it more compact. The greedy strategy is used to *optimally adapt* to the best representation based on the user requirements, amount of available data and resources, required resolution and so on. This powerful technique enables us to achieve the goal of compact biometric data representation, that allows for instance to efficiently store minor details of the modeled face (e.g. scars, wrinkles) or detailed patterns of the iris.

FUTURE TRENDS

In addition to data representation, adaptive technique can be highly useful in biometric feature extraction with the purpose of fast and reliable retrieval and matching of the biometric data, and in implementing dynamic

changes to the model. The methodology has a high potential of becoming one of the key approaches in biometric data modeling and synthesis.

CONCLUSION

The chapter reviewed the adaptive computational paradigm in application to surface modeling, evolutionary computing and biometric research. Some of the key future developments in the upcoming years will undoubtedly highlight the area, inspiring new generations of intelligent biometric systems with adaptive behavior.

KEY TERMS

Adaptive Geometric Model (AGM): A new approach to geometric computing utilizing adaptive computation paradigm. The model employs a continuous refinement criteria based on an error metric to optimally adapt to a more accurate representation.

Adaptive Multi-Resolution Technique (AMRT): For real-time terrain visualization is a method that utilizes a clever way of optimizing mesh dynamically for smooth and continuous visualization with a high efficiency.

Adaptive Spatial Memory (ASM): A hybrid method based on the combination of traditional hierarchical tree structure with the concept of expanding or collapsing tree nodes.

Biometric Technology (BT): An area of study of physical and behavioral characteristics with the purpose of person authentication and identification.

Delaunay Triangulation (DT): A computational geometry data structure dual to Voronoi diagram.

Evolutionary Paradigm (EP): The collective name for a number of problem solving methods utilizing principles of biological evolution, such as natural selection and genetic inheritance.

Swarm Intelligence (SI): The property of a system whereby the collective behaviors of unsophisticated agents interacting locally with their environment cause coherent functional global patterns to emerge.

Topology-Based Techniques (TBT): A group of methods using geometric properties of a set of objects in the space and their proximity

Voronoi Diagram (VD): A fundamental computational geometry data structure that stores topological information for a set of objects.

Adaptive Business Intelligence

Zbigniew Michalewicz

The University of Adelaide, Australia

INTRODUCTION

Since the computer age dawned on mankind, one of the most important areas in information technology has been that of “decision support.” Today, this area is more important than ever. Working in dynamic and ever-changing environments, modern-day managers are responsible for an assortment of far reaching decisions: *Should the company increase or decrease its workforce? Enter new markets? Develop new products? Invest in research and development?* The list goes on. But despite the inherent complexity of these issues and the ever-increasing load of information that business managers must deal with, all these decisions boil down to two fundamental questions:

- What is likely to happen in the future?
- What is the best decision right now?

Whether we realize it or not, these two questions pervade our everyday lives — both on a personal and professional level. When driving to work, for instance, we have to make a traffic prediction before we can choose the quickest driving route. At work, we need to predict the demand for our product before we can decide how much to produce. And before investing in a foreign market, we need to predict future exchange rates and economic variables. It seems that regardless of the decision being made or its complexity, we first need to make a prediction of what is likely to happen in the future, and then make the best decision based on that prediction. This fundamental process underpins the basic premise of *Adaptive Business Intelligence*.

BACKGROUND

Simply put, Adaptive Business Intelligence is the discipline of combining prediction, optimization, and adaptability into a system capable of answering these two fundamental questions: *What is likely to happen in the future?* and *What is the best decision right now?*

(Michalewicz et al. 2007). To build such a system, we first need to understand the methods and techniques that enable prediction, optimization, and adaptability (Dhar and Stein, 1997). At first blush, this subject matter is nothing new, as hundreds of books and articles have already been written on business intelligence (Vitt et al., 2002; Loshin, 2003), data mining and prediction methods (Weiss and Indurkha, 1998; Witten and Frank, 2005), forecasting methods (Makridakis et al., 1988), optimization techniques (Deb 2001; Coello et al. 2002; Michalewicz and Fogel, 2004), and so forth. However, none of these has explained how to combine these various technologies into a software system that is capable of predicting, optimizing, and adapting. *Adaptive Business Intelligence* addresses this very issue.

Clearly, the future of the business intelligence industry lies in systems that can make decisions, rather than tools that produce detailed reports (Loshin 2003). As most business managers now realize, there is a world of difference between having good knowledge and detailed reports, and making smart decisions. Michael Kahn, a technology reporter for Reuters in San Francisco, makes a valid point in the January 16, 2006 story entitled “Business intelligence software looks to future”:

“But analysts say applications that actually answer questions rather than just present mounds of data is the key driver of a market set to grow 10 per cent in 2006 or about twice the rate of the business software industry in general.”

‘Increasingly you are seeing applications being developed that will result in some sort of action,’ said Brendan Barnacle, an analyst at Pacific Crest Equities. ‘It is a relatively small part now, but it is clearly where the future is. That is the next stage of business intelligence.’”

MAIN FOCUS OF THE CHAPTER

“The answer to my problem is hidden in my data ... but I cannot dig it up!” This popular statement has been around for years as business managers gathered and stored massive amounts of data in the belief that they contain some valuable insight. But business managers eventually discovered that raw data are rarely of any benefit, and that their real value depends on an organization’s ability to analyze them. Hence, the need emerged for software systems capable of retrieving, summarizing, and interpreting data for end-users (Moss and Atre, 2003).

This need fueled the emergence of hundreds of *business intelligence* companies that specialized in providing software systems and services for extracting *knowledge* from raw data. These software systems would analyze a company’s operational data and provide knowledge in the form of tables, graphs, pies, charts, and other statistics. For example, a business intelligence report may state that 57% of customers are between the ages of 40 and 50, or that product X sells much better in Florida than in Georgia.¹

Consequently, the general goal of most business intelligence systems was to: (1) access data from a variety of different sources; (2) transform these data into information, and then into knowledge; and (3) provide an easy-to-use graphical interface to display this knowledge. In other words, a business intelligence system was responsible for collecting and digesting data, and presenting knowledge in a friendly way (thus enhancing the end-user’s ability to make good decisions). The diagram in Figure 1 illustrates the processes that underpin a traditional business intelligence system.

Although different texts have illustrated the relationship between data and knowledge in different ways (e.g.,

Davenport and Prusak, 2006; Prusak, 1997; Shortliffe and Cimino, 2006), the commonly accepted distinction between data, information, and knowledge is:

- *Data* are collected on a daily basis in the form of bits, numbers, symbols, and “objects.”
- *Information* is “organized data,” which are pre-processed, cleaned, arranged into structures, and stripped of redundancy.
- *Knowledge* is “integrated information,” which includes facts and relationships that have been perceived, discovered, or learned.

Because knowledge is such an essential component of any decision-making process (as the old saying goes, “*Knowledge is power!*”), many businesses have viewed knowledge as the final objective. But it seems that knowledge is no longer enough. A business may “know” a lot about its customers — it may have hundreds of charts and graphs that organize its customers by age, preferences, geographical location, and sales history — but management may still be unsure of what decision to make! And here lies the difference between “decision support” and “decision making”: all the knowledge in the world will not guarantee the right or best decision.

Moreover, recent research in psychology indicates that widely held beliefs can actually hamper the decision-making process. For example, common beliefs like “the more knowledge we have, the better our decisions will be,” or “we can distinguish between useful and irrelevant knowledge,” are not supported by empirical evidence. Having more knowledge merely increases our confidence, but it does not improve the accuracy of our decisions. Similarly, people supplied with “good” and “bad” knowledge often have trouble distinguishing

Figure 1. The processes that underpin a traditional business intelligence system

between the two, proving that irrelevant knowledge decreases our decision-making effectiveness.

Today, most business managers realize that a gap exists between having the right knowledge and making the right decision. Because this gap affects management's ability to answer fundamental business questions (such as "What should be done to increase profits? Reduce costs? Or increase market share?"), the future of business intelligence lies in systems that can provide answers and recommendations, rather than mounds of knowledge in the form of reports. *The future of business intelligence lies in systems that can make decisions!* As a result, there is a new trend emerging in the marketplace called *Adaptive Business Intelligence*. In addition to performing the role of traditional business intelligence (transforming data into knowledge), Adaptive Business Intelligence also includes the decision-making process, which is based on prediction and optimization as shown in Figure 2.

While *business intelligence* is often defined as "a broad category of application programs and technologies for gathering, storing, analyzing, and providing access to data," the term *Adaptive Business Intelligence* can be defined as "the discipline of using prediction and optimization techniques to build self-learning 'decisioning' systems" (as the above diagram shows). Adaptive Business Intelligence systems include elements of data mining, predictive modeling, forecasting, optimization, and adaptability, and are used by business managers to make better decisions.

This relatively new approach to business intelligence is capable of recommending the best course of action

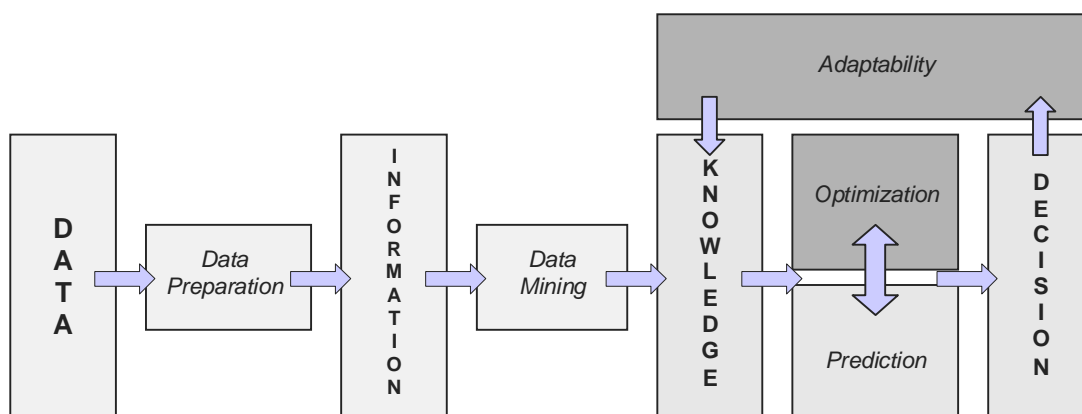

(based on past data), but it does so in a very special way: An Adaptive Business Intelligence system incorporates prediction and optimization modules to recommend near-optimal decisions, and an "adaptability module" for improving future recommendations. Such systems can help business managers make decisions that increase efficiency, productivity, and competitiveness. Furthermore, the importance of *adaptability* cannot be overemphasized. After all, what is the point of using a software system that produces sub par schedules, inaccurate demand forecasts, and inferior logistic plans, time after time? Would it not be wonderful to use a software system that could *adapt* to changes in the marketplace? A software system that could *improve* with time?

FUTURE TRENDS

The concept of adaptability is certainly gaining popularity, and not just in the software sector. Adaptability has already been introduced in everything from automatic car transmissions (which adapt their gear-change patterns to a driver's driving style), to running shoes (which adapt their cushioning level to a runner's size and stride), to Internet search engines (which adapt their search results to a user's preferences and prior search history). These products are very appealing for individual consumers, because, despite their mass production, they are capable of adapting to the preferences of each unique owner after some period of time.

The growing popularity of adaptability is also underscored by a recent publication of the US De-

Figure 2. Adaptive business intelligence system

partment of Defense. This lists 19 important research topics for the next decade and many of them include the term “adaptive”: *Adaptive Coordinated Control* in the Multi-agent 3D Dynamic Battlefield, *Control for Adaptive and Cooperative Systems*, *Adaptive System Interoperability*, *Adaptive Materials for Energy-Absorbing Structures*, and *Complex Adaptive Networks for Cooperative Control*.

For sure, adaptability was recognized as important component of intelligence quite some time ago: Alfred Binet (born 1857), French psychologist and inventor of the first usable intelligence test, defined intelligence as “... judgment, otherwise called good sense, practical sense, initiative, the faculty of *adapting* one’s self to circumstances.” Adaptability is a vital component of any intelligent system, as it is hard to argue that a system is “intelligent” if it does not have the capacity to adapt. For humans, the importance of adaptability is obvious: our ability to adapt was a key element in the evolutionary process. In psychology, a behavior or trait is adaptive when it helps an individual adjust and function well within a changing social environment. In the case of artificial intelligence, consider a chess program capable of beating the world chess master: Should we call this program intelligent? Probably not. We can attribute the program’s performance to its ability to evaluate the current board situation against a multitude of possible “future boards” before selecting the best move. However, because the program cannot learn or adapt to new rules, the program will lose its effectiveness if the rules of the game are changed or modified. Consequently, because the program is incapable of learning or adapting to new rules, the program is not intelligent.

The same holds true for any expert system. No one questions the usefulness of expert systems in some environments (which are usually well defined and static), but expert systems that are incapable of learning and adapting should not be called “intelligent.” Some expert knowledge was programmed in, that is all.

So, what are the future trends for Adaptive Business Intelligence? In words of Jim Goodnight, the CEO of SAS Institute (Collins et al. 2007):

“Until recently, business intelligence was limited to basic query and reporting, and it never really provided that much intelligence”

However, this is about to change. Keith Collins, the Chief Technology Officer of SAS Institute (Collins et al. 2007) believes that:

“A new platform definition is emerging for business intelligence, where BI is no longer defined as simple query and reporting. [...] In the next five years, we’ll also see a shift in performance management to what we’re calling predictive performance management, where analytics play a huge role in moving us beyond just simple metrics to more powerful measures.”

Further, Jim Davis, the VP Marketing of SAS Institute (Collins et al. 2007) stated:

“In the next three to five years, we’ll reach a tipping point where more organizations will be using BI to focus on how to optimize processes and influence the bottom line”

Finally, it would be important to incorporate *adaptability* in prediction and optimization components of the future Adaptive Business Intelligence systems.

There are some recent, successful implementations of Adaptive Business Intelligence systems reported (e.g., Michalewicz et al. 2005), which provide daily decision support for large corporations and result in multi-million dollars return on investment. There are also companies (e.g., www.solveitsoftware.com) which specialize in development of Adaptive Business Intelligence tools. However, further research effort is required. For example, most of the research in machine learning has focused on using historical data to build prediction models. Once the model is built and evaluated, the goal is accomplished. However, because new data arrive at regular intervals, building and evaluating a model is just the first step in Adaptive Business Intelligence. Because these models need to be updated regularly (something that the adaptability module is responsible for), we expect to see more emphasis on this updating process in machine learning research. Also, the frequency of updating the prediction module, which can vary from seconds (e.g., in real-time currency trading systems), to weeks and months (e.g., in fraud detection systems) may require different techniques and methodologies. In general, Adaptive Business Intelligence systems would include the research results from control theory, statistics, operations research, machine learning, and modern heuristic methods, to name a few. We also

expect that major advances will continue to be made in modern optimization techniques. In the years to come, more and more research papers will be published on constrained and multi-objective optimization problems, and on optimization problems set in dynamic environments. This is essential, as most real-world business problems are constrained, multi-objective, and set in a time-changing environment.

CONCLUSION

It is not surprising that the fundamental components of Adaptive Business Intelligence are already emerging in other areas of business. For example, the *Six Sigma* methodology is a great example of a well-structured, data-driven methodology for eliminating defects, waste, and quality-control problems in many industries. This methodology recommends the sequence of steps shown in Figure 3.

Note that the above sequence is very close “in spirit” to part of the previous diagram, as it describes (in more detail) the adaptability control loop. Clearly, we have to “measure,” “analyze,” and “improve,” as we operate in a dynamic environment, so the process of improvement is continuous. The SAS Institute proposes another methodology, which is more oriented towards data mining activities. Their methodology recommends the sequence of steps shown in Figure 4.

Again, note that the above sequence is very close to another part of our diagram, as it describes (in more detail) the transformation from data to knowledge. It is not surprising that businesses are placing considerable emphasis on these areas, because better decisions usually translate into better financial performance. And better financial performance is what Adaptive Business

Intelligence is all about. Systems based on Adaptive Business Intelligence aim at solving real-world business problems that have complex constraints, are set in time-changing environments, have several (possibly conflicting) objectives, and where the number of possible solutions is too large to enumerate. Solving these problems requires a system that incorporates modules for prediction, optimization, and adaptability.

TERMS AND DEFINITIONS

Adaptive Business Intelligence: The discipline of using prediction and optimization techniques to build self-learning ‘decisioning’ systems”.

Business Intelligence: A collection of tools, methods, technologies, and processes needed to transform data into actionable knowledge.

Data: Pieces collected on a daily basis in the form of bits, numbers, symbols, and “objects.”

Data Mining: The application of analytical methods and tools to data for the purpose of identifying patterns, relationships, or obtaining systems that perform useful tasks such as classification, prediction, estimation, or affinity grouping.

Information: “Organized data,” which are preprocessed, cleaned, arranged into structures, and stripped of redundancy.

Knowledge: “Integrated information,” which includes facts and relationships that have been perceived, discovered, or learned.

Optimization: Process of finding the solution that is the best fit to the available resources.

Prediction: A statement or claim that a particular event will occur in the future.

ENDNOTE

¹ Note that *business intelligence* can be defined both as a “state” (a report that contains knowledge) and a “process” (software responsible for converting data into knowledge).

Adaptive Neural Algorithms for PCA and ICA

Radu Muthiac

University of Bucharest, Romania

INTRODUCTION

Artificial neural networks (ANNs) (McCulloch & Pitts, 1943) (Haykin, 1999) were developed as models of their biological counterparts aiming to emulate the real neural systems and mimic the structural organization and function of the human brain. Their applications were based on the ability of self-designing to solve a problem by learning the solution from data. A comparative study of neural implementations running principal component analysis (PCA) and independent component analysis (ICA) was carried out. Artificially generated data additively corrupted with white noise in order to enforce randomness were employed to critically evaluate and assess the reliability of data projections. Analysis in both time and frequency domains showed the superiority of the estimated independent components (ICs) relative to principal components (PCs) in faithful retrieval of the genuine (latent) source signals.

Neural computation belongs to information processing dealing with adaptive, parallel, and distributed (localized) signal processing. In data analysis, a common task consists in finding an adequate subspace of multivariate data for subsequent processing and interpretation. Linear transforms are frequently employed in data model selection due to their computational and conceptual simplicity. Some common linear transforms are PCA, factor analysis (FA), projection pursuit (PP), and, more recently, ICA (Comon, 1994). The latter emerged as an extension of nonlinear PCA (Hotelling, 1993) and developed in the context of blind source separation (BSS) (Cardoso, 1998) in signal and array processing. ICA is also related to recent theories of the visual brain (Barlow, 1991), which assume that consecutive processing steps lead to a progressive reduction in the redundancy of representation (Olshausen and Field, 1996).

This contribution is an overview of the PCA and ICA neuromorphic architectures and their associated algorithmic implementations increasingly used as exploratory techniques. The discussion is conducted on artificially generated sub- and super-Gaussian source signals.

BACKGROUND

In neural computation, transforming methods amount to unsupervised learning, since the representation is only learned from data without any external control. Irrespective of the nature of learning, the neural adaptation may be formally conceived as an optimization problem: an objective function describes the task to be performed by the network and a numerical optimization procedure allows adapting network parameters (e.g., connection weights, biases, internal parameters). This process amounts to search or nonlinear programming in a quite large parameter space. However, any prior knowledge available on the solution might be efficiently exploited to narrow the search space. In supervised learning, the additional knowledge is incorporated in the net architecture or learning rules (Gold, 1996). A less extensive research was focused on unsupervised learning. In this respect, the mathematical methods usually employed are drawn from classical constrained multivariate nonlinear optimization and rely on the Lagrange multipliers method, the penalty or barrier techniques, and the classical numerical algebra techniques, such as deflation/renormalization (Fiori, 2000), the Gram-Schmidt orthogonalization procedure, or the projection over the orthogonal group (Yang, 1995).

PCA and ICA Models

Mathematically, the linear stationary PCA and ICA models can be defined on the basis of a common data model. Suppose that some stochastic processes are represented by three random (column) vectors $\mathbf{x}(t)$, $\mathbf{n}(t) \in \mathbb{R}^N$ and $\mathbf{s}(t) \in \mathbb{R}^M$ with zero mean and finite covariance, with the components of $\mathbf{s}(t) = \{s_1(t), s_2(t), \dots, s_M(t)\}$ being statistically independent and at most one Gaussian. Let \mathbf{A} be a rectangular constant full column rank $N \times M$ matrix with at least as many rows as columns ($N \geq M$), and denote by t the sample index (i.e., time or sample point) taking the discrete values $t = 1, 2, \dots$,

T . We postulate the existence of a linear relationship among these variables like:

$$\mathbf{x}(t) = \mathbf{A}\mathbf{s}(t) + \mathbf{n}(t) = \sum_{i=1}^M s_i(t) \mathbf{a}_i + \mathbf{n}(t) \quad (1)$$

Here $\mathbf{s}(t)$, $\mathbf{x}(t)$, $\mathbf{n}(t)$, and \mathbf{A} are the sources, the observed data, the (unknown) noise in data, and the (unknown) mixing matrix, respectively, whereas \mathbf{a}_i , $i = 1, 2, \dots, M$ are the columns of \mathbf{A} . Mixing is supposed to be instantaneous, so there is no time delay between a (latent) source variable $s_i(t)$ mixing into an observable (data) variable $x_j(t)$, with $i = 1, 2, \dots, M$ and $j = 1, 2, \dots, N$.

Consider that the stochastic vector process $\{\mathbf{x}(t)\} \in \mathbb{R}^N$ has the mean $E\{\mathbf{x}(t)\} = 0$ and the covariance matrix $\mathbf{C}_x = E\{\mathbf{x}(t) \mathbf{x}(t)^T\}$. The goal of PCA is to identify the dependence structure in each dimension and to come out with an orthogonal transform matrix \mathbf{W} of size $L \times N$ from \mathbb{R}^N to \mathbb{R}^L , $L < N$, such that the L -dimensional output vector $\mathbf{y}(t) = \mathbf{W} \mathbf{x}(t)$ sufficiently represents the intrinsic features of the input data, and where the covariance matrix \mathbf{C}_y of $\{\mathbf{y}(t)\}$ is a diagonal matrix \mathbf{D} with the diagonal elements arranged in descending order, $d_{i,i} \geq d_{i+1,i+1}$. The restoration of $\{\mathbf{x}(t)\}$ from $\{\mathbf{y}(t)\}$, say $\{\hat{\mathbf{x}}(t)\}$, is consequently given by $\hat{\mathbf{x}}(t) = \mathbf{W}^T \mathbf{W} \mathbf{x}(t)$ (Figure 1). For a given L , PCA aims to find an optimal value of \mathbf{W} , such as

to minimize the error function $J = E\|\mathbf{x}(t) - \hat{\mathbf{x}}(t)\|^2$. The rows in \mathbf{W} are the PCs of the stochastic process $\{\mathbf{x}(t)\}$ and the eigenvectors \mathbf{c}_j , $j = 1, 2, \dots, L$ of the input covariance matrix \mathbf{C}_x . The subspace spanned by the principal eigenvectors $\{\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_L\}$ with $L < N$, is called the PCA subspace of dimensionality L .

The ICA problem can be formulated as following:

given T realizations of $\mathbf{x}(t)$, estimate both the matrix \mathbf{A} and the corresponding realizations of $\mathbf{s}(t)$. In BSS the task is somewhat relaxed to finding the waveforms $\{s_i(t)\}$ of the sources knowing only the (observed) mixtures $\{x_j(t)\}$. If no suppositions are made about the noise, the additive noise term is omitted in (1). A practical strategy is to include noise in the signals as supplementary term(s): hence the ICA model (Fig. 2) becomes:

$$\mathbf{x}(t) = \mathbf{A}\mathbf{s}(t) = \sum_{i=1}^M \mathbf{a}_i s_i(t) \quad (2)$$

The source separation consists in updating an unmixing matrix $\mathbf{B}(t)$, without resorting to any information about the spatial mixing matrix \mathbf{A} , so that the output vector $\mathbf{y}(t) = \mathbf{B}(t) \mathbf{x}(t)$ becomes an estimate $\mathbf{y}(t) = \hat{\mathbf{s}}(t)$ of the original independent source signals $\mathbf{s}(t)$. The separating matrix $\mathbf{B}(t)$ is divided in two parts dealing with dependencies in the first two moments, i.e., the whitening matrix $\mathbf{V}(t)$, and the dependencies in

Figure 1. Schematic of the PCA model

Figure 2. Schematic of the ICA model

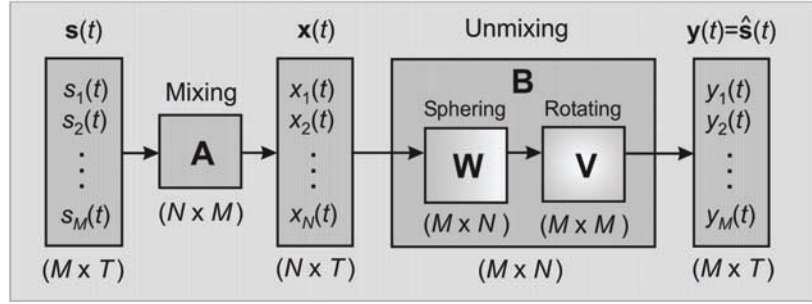

Figure 3. A simple feed-forward ANN performing PCA and ICA

higher-order statistics, i.e., the orthogonal separating matrix $\mathbf{W}(t)$ in the whitened space (Fig. 2). If we assume zero-mean observed data $\mathbf{x}(t)$, then we get by whitening a vector $\mathbf{v}(t) = \mathbf{V}(t) \mathbf{x}(t)$ with decorrelated components. The subsequent linear transform $\mathbf{W}(t)$ seeks the solution by an adequate rotation in the space of component densities and yields $\mathbf{y}(t) = \mathbf{W}(t) \mathbf{v}(t)$ (Fig. 2). The total separation matrix between the input and the output layer turns to be $\mathbf{B}(t) = \mathbf{W}(t) \mathbf{V}(t)$. In the standard stationary case, the whitening and the orthogonal separating matrices converge to some constant values after a finite number of iterations during learning, that is, $\mathbf{B}(t) \rightarrow \mathbf{B} = \mathbf{W} \mathbf{V}$.

NEURAL IMPLEMENTATIONS

A neural approach to BSS entails a network that has mixtures of the source signals as input and produces approximations of the source signals as output (Figure 3). As a prerequisite, the input signals must be mutually uncorrelated, a requirement usually fulfilled by PCA. The output signals must nevertheless be mutually independent, which leads in a natural way from PCA to ICA. The higher order statistics required by source separation can be incorporated into computations either explicitly or by using suitable nonlinearities. ANNs better fit the latter approach (Karhunen, 1996).

The core of the large class of neural adaptive algorithms consists in a learning rule and its associated optimization criterion (objective function). These two items differentiate the algorithms, which are actually families of algorithms parameterized by the nonlinear

function used. An update rule is specified by the iterative incremental change $\Delta \mathbf{W}$ of the rotation matrix \mathbf{W} , which gives the general form of the learning rule:

$$\mathbf{W} \rightarrow \mathbf{W} + \Delta \mathbf{W} \quad (3)$$

Neural PCA

First, consider a single artificial neuron receiving an M -dimensional input vector \mathbf{x} . It gradually adapts its

weight vector \mathbf{w} so that the function $E \{f(\mathbf{w}^T \mathbf{x})\}$ is maximized, where E is the expectation with respect to the (unknown) probability density of \mathbf{x} and f is a continuous objective function. The function f is bounded by setting constant the Euclidian norm of \mathbf{w} . A constrained gradient ascent learning rule based on a sequence of sample functions for relatively small learning rates $\alpha(t)$ is then (Oja, 1995):

$$\mathbf{w}(t+1) = \mathbf{w}(t) + \alpha(t) (\mathbf{I} - \mathbf{w}(t)^T \mathbf{w}(t)) \mathbf{x}(t) g(\mathbf{w}(t)^T \mathbf{w}(t)) \quad (4)$$

where $g = f'$. Any PCA learning rules tend to find that direction in the input space along which the data has maximal variance. If all directions in the input space have equal variance, the one-unit case with a suitable nonlinearity is approximately minimizing the kurtosis of the neuron input. It means that the weight vector of the unit will be determined by the direction in the input space on which the projection of the input data is mostly clustered and deviates significantly from normality. This task is essentially the goal in the PP technique.

In the case of single layer ANNs consisting of L parallel units, with each unit i having the same M -element input vector \mathbf{x} and its own weight vector \mathbf{w}_i that together comprise an $M \times L$ weight matrix

$\mathbf{W} = [\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_L]$ the following training rule obtained from (4) is a generalization of the linear PCA learning rule (in matrix form):

$$\mathbf{W}(t+1) = \mathbf{W}(t) + \alpha(t) (\mathbf{I} - \mathbf{W}(t) \mathbf{W}(t)^T) \mathbf{x}(t) g(\mathbf{x}(t)^T \mathbf{W}(t)) \quad (5)$$

Due to the instability of the above nonlinear Hebbian learning rule for the multi-unit case, a different approach based on optimizing two criteria simultaneously was introduced (Oja, 1982):

$$\mathbf{W}(t+1) = \mathbf{W}(t) + \mu(t) \mathbf{x}(t) g(\mathbf{y}(t)^T) + \gamma(t) (\mathbf{I} - \mathbf{W}(t) \mathbf{W}(t)^T) \quad (6)$$

Here $\mu(t)$ is chosen positive or negative depending on our interest in maximizing or minimizing, respec-

tively, the objective function $J_1(\mathbf{w}_i) = E \{f(\mathbf{x}^T \mathbf{w}_i)\}$. Similarly, $\gamma(t)$ is another gain parameter that is always positive and constrains the weight vectors to orthonormality, which is imposed by an appropriate penalty function such as:

$$J_2(\mathbf{w}_i) = \frac{1}{2} (1 - \mathbf{w}_i^T \mathbf{w}_i)^2 + \frac{1}{2} \sum_{j=1, j \neq i}^M (\mathbf{w}_i^T \mathbf{w}_j)^2.$$

This is the bigradient algorithm, which is iterated until the weight vectors have converged with the desired accuracy. This algorithm can use normalized Hebbian or anti-Hebbian learning in a unified formula. Starting from one-unit rule, the multi-unit bigradient algorithm can simultaneously extract several robust counterparts of the principal or minor eigenvectors of the data covariance matrix (Wang, 1996).

In the case of multilayered ANNs, the transfer functions of the hidden nodes can be expressed by radial basis functions (RBF), whose parameters could be learnt by a two-stage gradient descent strategy. A new growing RBF-node insertion strategy with different RBF is used in order to improve the net performances. The learning strategy is reported to save computational time and memory space in approximation of continuous and discontinuous mappings (Esposito *et al.*, 2000).

Neural ICA

Various forms of unsupervised learning have been implemented in ANNs beyond standard PCA like nonlinear PCA and ICA. Data whitening can be neurally emulated by PCA with a simple iterative algorithm that updates the sphering matrix $\mathbf{V}(t)$:

$$\mathbf{V}(t+1) = \mathbf{V}(t) - \alpha(t)(\mathbf{v}\mathbf{v}^T - \mathbf{I}) \quad (7)$$

After getting the decorrelation matrix $\mathbf{V}(t)$, the basic task for ICA algorithms remains to come out with an orthogonal matrix $\mathbf{W}(t)$, which is equivalent to a suitable rotation of the decorrelated data $\mathbf{v}(t) = \mathbf{V}(t)\mathbf{x}(t)$ aiming to maximize the product of the marginal densities of its components. There are various neural approaches to estimate the rotation matrix $\mathbf{W}(t)$. An important class of algorithms is based on maximization of network entropy (Bell, 1995). The BS nonlinear information maximization (infomax) algorithm performs online stochastic gradient ascent in mutual information (MI) between outputs and inputs of a network. By minimizing the MI between outputs, the network factorizes the inputs into independent components. Considering a network with the input vector $\mathbf{x}(t)$, a weight matrix $\mathbf{W}(t)$, and a monotonically transformed output vector $\mathbf{y} = g(\mathbf{W}\mathbf{x} + \mathbf{w}_0)$, then the resulting learning rule for the weights and bias-weights, respectively, are:

$$\Delta\mathbf{W} = [\mathbf{W}^T]^{-1} + \mathbf{x}(\mathbf{1} - 2\mathbf{y})^T \quad \text{and} \quad \Delta\mathbf{w}_0 = \mathbf{1} - 2\mathbf{y} \quad (8)$$

In the case of bounded variables, the interplay between the anti-Hebbian term $\mathbf{x}(\mathbf{1} - 2\mathbf{y})^T$ and the antidecay term $[\mathbf{W}^T]^{-1}$ produces an output density that is close to the flat constant distribution, which corresponds to the maximum entropy distribution. Amari, Cichocki, and Yang (Amari, 1996) altered the BS infomax algorithm by using the natural gradient instead of the stochastic gradient to reduce the complexity of neural computations and significantly improving the speed of convergence. The update rule proposed for the separating matrix is:

$$\Delta\mathbf{W} = [\mathbf{I} - g(\mathbf{W}\mathbf{x})(\mathbf{W}\mathbf{x})^T] \mathbf{W} \quad (9)$$

Lee *et al.* (Lee, 2000) extended to both sub- and super-Gaussian distributions the learning rule devel-

oped from the infomax principle satisfying a general stability criterion and preserving the simple initial architecture of the network. Applying either natural or relative gradient (Cardoso, 1996) for optimization, their learning rule yields results that compete with fixed-point batch computations.

The equivariant adaptive separation via independence (EASI) algorithm introduced by Cardoso and Laheld (1996) is a nonlinear decorrelation method. The objective function $J(\mathbf{W}) = E\{f(\mathbf{W}\mathbf{x})\}$ is subject to minimization with the orthogonal constraint imposed on \mathbf{W} and the nonlinearity $g = f'$ chosen according to data kurtosis. Its basic update rule equates to:

$$\Delta\mathbf{W} = -\lambda (\mathbf{y}\mathbf{y}^T - \mathbf{I} + g(\mathbf{y})\mathbf{y}^T - \mathbf{y}g(\mathbf{y}^T))\mathbf{W} \quad (10)$$

Fixed-point (FP) algorithms are searching the ICA solution by minimizing mutual information (MI) among the estimated components (Hyvärinen, 1997). The FastICA learning rule finds a direction \mathbf{w} so that the projection of $\mathbf{w}^T\mathbf{x}$ maximizes a contrast function

of the form $J_G(\mathbf{w}) = [E\{f(\mathbf{w}^T\mathbf{x})\} - E\{f(\mathbf{v})\}]^2$ with \mathbf{v} standing for the standardized Gaussian variable. The learning rule is basically a Gram-Schmidt-like decorrelation method.

ALGORITHM ASSESSMENT

We comparatively run both PCA and ICA neural algorithms using synthetically generated time series additively corrupted with some white noise to alleviate strict determinism (Table 1 and Fig. 4.). Neural PCA was implemented using the bigradient algorithm since it works for both minimization and maximization of the criterion J_1 under the normality constraints enforced by the penalty function J_2 .

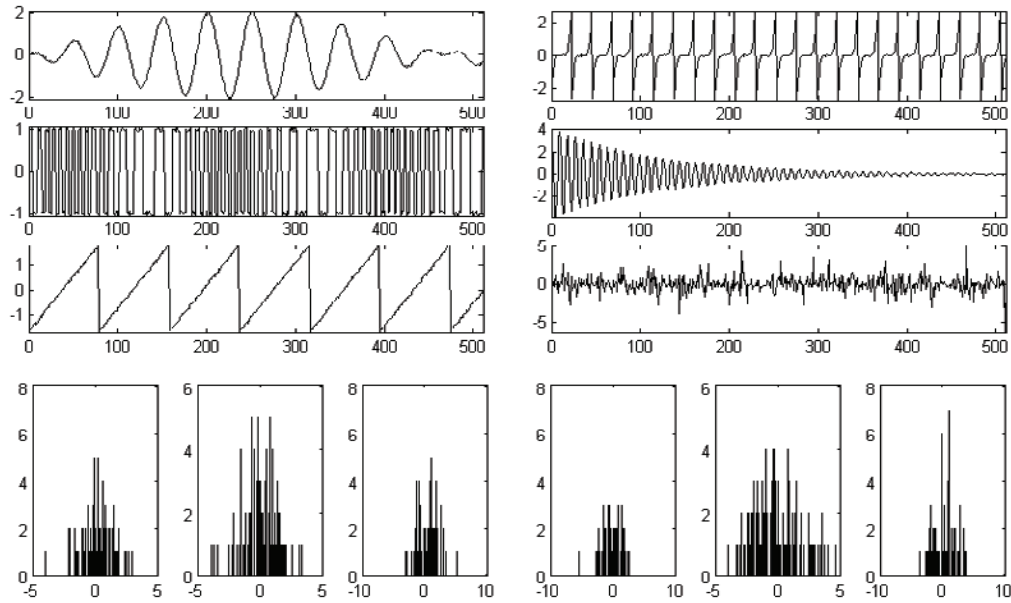

The neural ICA algorithms were the extended infomax of Bell and Sejnowski, a semi-adaptive fixed-point fast ICA algorithm (Hyvärinen & Oja, 1997), an adapted variant of EASI algorithm optimized for real data, and the extended generalized lambda distribution (EGLD) maximum likelihood-based algorithm.

In the case of artificially generated sources, the accuracy of separating the latent sources by an algorithm

Figure 4. Sub-Gaussian (left) and super-Gaussian (right) source signals and their corresponding histograms (bottom)

performing ICA can be measured by means of some quantitative indexes. The first we used was defined as the signal-to-interference ratio (*SIR*):

$$SIR = \frac{1}{N} \sum_{i=1}^N 10 \cdot \log_{10} \frac{\max(Q_i)^2}{Q_i^T Q_i - \max(Q_i)^2} \quad (11)$$

where $\mathbf{Q} = \mathbf{BA}$ is the overall transforming matrix of the latent source components, Q_i is the i -th column of \mathbf{Q} , $\max(Q_i)$ is the maximum element of Q_i , and N is the number of the source signals. The higher the *SIR* is, the better the separation performance of the algorithm.

A secondly employed index was the distance between the overall transforming matrix \mathbf{Q} and an ideal permutation matrix, which is interpreted as the cross-talking error (*CTE*):

$$CTE = \sum_{i=1}^N \left(\sum_{j=1}^N \frac{|Q_{ij}|}{\max |Q_i|} - 1 \right) + \sum_{j=1}^N \left(\sum_{i=1}^N \frac{|Q_{ij}|}{\max |Q_j|} - 1 \right) \quad (12)$$

Above, Q_{ij} is the ij -th element of \mathbf{Q} , $\max |Q_i|$ is the maximum absolute valued element of the row i

in \mathbf{Q} , and $\max |Q_j|$ is the maximum absolute valued element of the column j in \mathbf{Q} . A permutation matrix is defined so that on each of its rows and columns, only one of the elements equals to unity while all the other elements are zero. It means that the *CTE* attains its minimum value zero for an exact permutation matrix (i.e., perfect decomposition) and goes positively higher the more \mathbf{Q} deviates from a permutation matrix (i.e., decomposition of lower accuracy).

We defined the relative signal retrieval error (*SRE*) as the Euclidian distance between the source signals and their best matching estimated components normalized to the number of source

signals, times the number of time samples, and times the module of the source signals:

$$SRE = \frac{1}{TN} \sqrt{\frac{\sum_{i=1}^N \left(\sum_{t=1}^T [x_i(t) - y_i(t)]^2 \right)}{\sum_{i=1}^N \left(\sum_{t=1}^T [x_i(t)]^2 \right)}}, \quad t = 1, 2, \dots, T \quad (13)$$

The lower the *SRE* is, the better the estimates approximate the latent source signals.

The stabilized version of FastICA algorithm is attractive by its fast and reliable convergence, and by the lack of parameters to be tuned. The natural gradient incorporated in the BS extended infomax performs better than the original gradient ascent and is computationally less demanding. Though the BS algorithm is theoretically optimal in the sense of dealing with mutual information as objective function, like all neural unsupervised algorithms, its performance heavily depends on the learning rates and its convergence is rather slow. The EGLD algorithm separates skewed distributions, even for zero kurtosis. In terms of computational time, the BS extended infomax algorithm was the fastest, FastICA more faithfully retrieved the sources among all algorithms under test, while the EASI algorithm came out with a full transform matrix \mathbf{Q} that is the closest to unity.

FUTURE TRENDS

Neuromorphic methods in exploratory analysis and data mining are rapidly emerging applications of unsupervised neural training. In recent years, new learning algorithms have been proposed, yet their theoretical properties, range of optimal applicability, and comparative assessment have remained largely unexplored. No convergence theorems are associated with the training algorithms in use. Moreover, algorithm convergence heavily depends on the proper choice of the learning rate(s) and, even when convergence is accomplished, the neural algorithms are relatively slow compared with batch-type computations. Nonlinear and nonstationary neural ICA is expected to be developed due to ANNs

nonalgorithmic processing and their ability to learn nonanalytical relationships if adequately trained.

CONCLUSION

Both PCA and ICA share some common features like aiming at building generative models that are likely to have produced the observed data and performing information preservation and redundancy reduction. In a neuromorphic approach, the model parameters are treated as network weights that are changed during the learning process. The main difficulty in function approximation stems from choosing the network parameters that have to be fixed a priori, and those that must be learnt by means of an adequate training rule.

PCA and ICA have major applications in data mining and exploratory data analysis, such as signal characterization, optimal feature extraction, and data compression, as well as the basis of subspace classifiers in pattern recognition. ICA is much better suited than PCA to perform BSS, blind deconvolution, and equalization.

KEY TERMS

Artificial Neural Networks (ANNs): An information-processing synthetic system made up of several simple nonlinear processing units connected by elements that have information storage and programming functions adapting and learning from patterns, which mimics a *biological* neural network.

Blind Source Separation (BSS): Separation of latent nonredundant (e.g., mutually statistically independent or decorrelated) source signals from a set of linear mixtures, such that the regularity of each resulting signal is maximized, and the regularity between the signals is minimized (i.e. statistical independence is maximized) without (almost) any information on the sources.

Confirmatory Data Analysis (CDA): An approach which, subsequent to data acquisition, proceeds with the imposition of a prior model and analysis, estimation, and testing model parameters.

Exploratory Data Analysis (EDA): An approach based on allowing the data itself to reveal its underlying structure and model heavily using the collection of techniques known as *statistical graphics*.

Independent Component Analysis (ICA): An exploratory method for separating a linear mixture of latent signal sources into independent components as optimal estimates of the original sources on the basis of their mutual statistical independence and non-Gaussianity.

Learning Rule: Weight change strategy in a connectionist system aiming to optimize a certain objective function. Learning rules are iteratively applied to the training set inputs with error gradually reduced as the weights are adapting.

Principal Component Analysis (PCA): An orthogonal linear transform based on singular value decomposition that projects data to a subspace that preserves maximum variance.

Adaptive Neuro–Fuzzy Systems

INTRODUCTION

Fuzzy logic became the core of a different approach to computing. Whereas traditional approaches to computing were precise, or hard edged, fuzzy logic allowed for the possibility of a less precise or softer approach (Klir et al., 1995, pp. 212-242). An approach where precision is not paramount is not only closer to the way humans thought, but may be in fact easier to create as well (Jin, 2000). Thus was born the field of soft computing (Zadeh, 1994). Other techniques were added to this field, such as Artificial Neural Networks (ANN), and genetic algorithms, both modeled on biological systems. Soon it was realized that these tools could be combined, and by mixing them together, they could cover their respective weaknesses while at the same time generate something that is greater than its parts, or in short, creating synergy.

Adaptive Neuro-fuzzy is perhaps the most prominent of these admixtures of soft computing technologies (Mitra et al., 2000). The technique was first created when artificial neural networks were modified to work with fuzzy logic, hence the Neuro-fuzzy name (Jang et al., 1997, pp. 1-7). This combination provides fuzzy systems with adaptability and the ability to learn. It was later shown that adaptive fuzzy systems could be created with other soft computing techniques, such as genetic algorithms (Yen et al., 1998, pp. 469-490), Rough sets (Pal et al., 2003; Jensen et al., 2004, Ang et al., 2005) and Bayesian networks (Muller et al., 1995), but the Neuro-fuzzy name was widely used, so it stayed. In this chapter we are using the most widely used terminology in the field.

Neuro-fuzzy is a blanket description of a wide variety of tools and techniques used to combine any aspect of fuzzy logic with any aspect of artificial neural

networks. For the most part, these combinations are just extensions of one technology or the other. For example, neural networks usually take binary inputs, but use weights that vary in value from 0 to 1. Adding fuzzy sets to ANN to convert a range of input values into values that can be used as weights is considered a Neuro-fuzzy solution. This chapter will pay particular interest to the sub-field where the fuzzy logic rules are modified by the adaptive aspect of the system.

The next part of this chapter will be organized as follows: in section 1 we examine models and techniques used to combine fuzzy logic and neural networks together to create Neuro-fuzzy systems. Section 2 provides an overview of the main steps involved in the development of adaptive Neuro-fuzzy systems. Section 3 concludes this chapter with some recommendations and future developments.

NEURO-FUZZY TECHNOLOGY

Neuro-fuzzy Technology is a broad term used to describe a field of techniques and methods used to combine fuzzy logic and neural networks together (Jin, 2003, pp. 111-140). Fuzzy logic and neural networks each have their own sets of strengths and weaknesses, and most attempts to combine these two technologies have the goal of using each techniques strengths to cover the others weaknesses.

Neural networks are capable of self-learning, classification and associating inputs with outputs. Neural networks can also become a universal function approximator (Kosko, 1997, pp. 299; Nauck et al., 1998, Nauck et al. 1999). Given enough information about an unknown continuous function, such as its inputs

and outputs, the neural network can be trained to approximate it. The disadvantages of neural networks are they are not guaranteed to converge, that is to be trained properly, and after they have been trained they cannot give any information about why they take a particular course of action when given a particular input.

Fuzzy logic Inference systems can give human readable and understandable information about why a particular course of action was taken because it is governed by a series of IF THEN rules. Fuzzy logic systems can adapt in a way that their rules and the parameters of the fuzzy sets associated with those rules can be changed to meet some criteria. However fuzzy logic systems lack the capability for self-learning, and must be modified by an external entity. Another salient feature of fuzzy logic systems is that they are, like artificial neural networks, capable of acting as universal approximators.

The common feature of being able to act as a universal approximator is the basis of most attempts to merge these two technologies. Not only it can be used to approximate a function but it can also be used by both neural networks, and fuzzy logic systems to approximate each other as well. (Pal et al., 1999, pp. 66)

Universal approximation is the ability of a system to replicate a function to some degree. Both neural networks and fuzzy logic systems do this by using a non-mathematical model of the system (Jang et al., 1997, pp. 238; Pal et al., 1999, pp. 19). The term approximate is used as the model does not have to match the simulated function exactly, although it is sometime possible to do so if enough information about the function is available. In most cases it is not necessary or even desirable to perfectly simulate a function as this takes time and resources that may not be available and close is often good enough.

Categories of Neuro-Fuzzy Systems

Efforts to combine fuzzy logic and neural networks have been underway for several years and many methods have been attempted and implemented. These methods are of two major categories:

- **Fuzzy Neural Networks (FNN):** are neural networks that can use fuzzy data, such as fuzzy rules, sets and values (Jin, 2003, pp.205-220).

- **Neural-Fuzzy Systems (NFS):** are fuzzy systems “augmented” by neural networks (Jin, 2003, pp.111-140).

There also four main architectures used for implementing neuro-fuzzy systems:

- **Fuzzy Multi-layer networks** (Jang, 1993; Mitra et al., 1995; Mitra et al., 2000; Mamdani et al., 1999; Sugeno et al., 1988, Takagi et al., 1985).
- **Fuzzy Self-Organizing Map networks** (Drobnic et al., 2000; Kosko, 1997, pp. 98; Haykin, 1999, pp. 443)
- **Black-Box Fuzzy ANN** (Bellazzi et al., 1999; Qiu, 2000; Monti, 1996)
- **Hybrid Architectures** (Zatwarnicki, 2005; Borzemski et al., 2003; Marichal et al., 2001; Rahmoun et al., 2001; Koprinska et al., 2000; Wang et al. 1999; Whitfort et al., 1995).

DEVELOPMENT OF ADAPTIVE NEURO-FUZZY SYSTEMS

Developing an Adaptive Neuro-fuzzy system is a process that is similar to the procedures used to create fuzzy logic systems, and neural networks. One advantage of this combined approach is that it is usually no more complicated than either approach taken individually.

As noted above, there are two methods of creating a Neuro-fuzzy system; integrating fuzzy logic into a neural network framework (FNN), and implementing neural networks into a fuzzy logic system (NFS). A fuzzy neural network is just a neural network with some fuzzy logic components; hence is generally trained like a normal neural network is.

Training Process: The training regimen for a NFS differs slightly from that used to create a neural network and a fuzzy logic system in some key ways, while at the same time incorporating many improvements over those training methods.

The training process of a Neuro-fuzzy system has five main steps: (Von Altrock, 1995, pp. 71-75)

- **Obtain Training Data:** The data must cover all possible inputs and output, and all the critical regions of the function if it is to model it in an appropriate manner.

- **Create a Fuzzy Logic System:** The fuzzy system may be an existing system which is known to work, such as one that has been in production for some time or one that has been created by following expert system development methodologies.
- **Define the Neural Fuzzy Learning:** This phase deals with defining what you want the system to learn. This allows greater control over the learning process while still allowing for rule knowledge discovery.
- **Training Phase:** To run the training algorithm. The algorithm may have parameters that can be adjusted to modify how the system is to be modified during training.
- **Optimization and Verification:** Validation can take many forms, but will usually involve feeding the system a series of known inputs to determine if the system generates the desired output, and or is within acceptable parameters. Furthermore, the rules and membership functions may be extracted so they can be examined by human experts for correctness.

CONCLUSION AND FUTURE DEVELOPMENTS

Advantages of ANF systems: Although there are many ways to implement a Neuro-fuzzy system, the advantages described for these systems are remarkably uniform across the literature. The advantages attributed to Neuro-fuzzy systems as compared to ANNs are usually related to the following aspects:

- **Faster to train:** This is due to the massive number of connections present in the ANN, and the non-trivial number of calculations associated with each. As well, most neural fuzzy systems can be trained by going through the data once, whereas a neural network may need to be exposed to the same training data many times before it converges.
- **Less computational resources:** Neural fuzzy system is smaller in size and contains fewer internal connections than a comparable ANN, hence it is faster and use significantly less resources.
- **Offer the possibility to extract the rules:** This is a major advantage over ANNs in that the rules governing a system can be communicated to the human users in an easily understandable form.

Limitation of ANF systems: The greatest limitation in creating adaptive systems is known as the “Curse of Dimensionality”, which is named after the exponential growth in the number of features that the model has to keep track of as the number of input attributes increases. Each attribute in the model is a variable in the system, which corresponds to an axis in a multidimensional graph that the function is mapped into. The connections between different attributes correspond to the number of potential rules in the system as given by the formula:

$$N_{\text{rules}} = (L_{\text{linguistic_terms}})^{\text{variables}} \text{ (Gorrostieta et al., 2006)}$$

This formula becomes more complicated if there are different numbers of linguistic variables (fuzzy sets) covering each attribute dimension. Fortunately there are ways around this problem. As the neural fuzzy system is only approximating the function being modeled, the system may not need all the attributes to achieve the desired results.

Another area of criticism in the Neuro-fuzzy field is related to aspects that can't be learned or approximated. One of the most known aspects here is the caveat attached to the universal approximation. In fact, the function being approximated has to be continuous; a continuous function is a function that does not have a singularity, a point where it goes to infinity. Other functions that Adaptive Neuro-fuzzy systems may have problems learning are things like encryption algorithms, which are purposely designed to be resistant to this type of analysis.

Future developments: Predicting the future has always been hard; however for ANF technology the future expansion has been made easy because of the widespread use of its basis technology (neural networks and fuzzy logic). Mixing of these technologies creates synergies as they remediate to each other weaknesses. ANF technology allows complex system to be grown instead of someone having to build them.

One of the most promising areas for ANF systems is System Mining. There exist many cases where we wish to automate a system that cannot be systematically described in a mathematical manner. This means there is no way of creating a system using classical development methodologies (i.e. Programming a simulation.). If we have an adequately large set of examples of inputs and their corresponding outputs, ANF can be used to get a model of the system. The rules and their associated

fuzzy sets can then be extracted from this system and examined for details about how the system works. This knowledge can be used to build the system directly. One interesting application of this technology is to audit existing complex systems. The extracted rules could be used to determine if the rules match the exceptions of what the system is supposed to do, and even detect fraud actions. Alternatively, the extracted model may show an alternative, and or more efficient manner of implementing the system.

KEY TERMS

Artificial Neural Networks (ANN): An artificial neural network, often just called a “neural network” (NN), is an interconnected group of artificial neurons that uses a mathematical model or computational model for information processing based on a connectionist approach to computation. Knowledge is acquired by the network from its environment through a learning process, and interneuron connection strengths (synaptic weights) are used to store the acquired knowledge.

Evolving Fuzzy Neural Network (EFuNN): An Evolving Fuzzy Neural Network is a dynamic architecture where the rule nodes grow if needed and shrink by aggregation. New rule units and connections can be added easily without disrupting existing nodes.

The learning scheme is often based on the concept of “winning rule node”.

Fuzzy Logic: Fuzzy logic is an application area of fuzzy set theory dealing with uncertainty in reasoning. It utilizes concepts, principles, and methods developed within fuzzy set theory for formulating various forms of sound approximate reasoning. Fuzzy logic allows for set membership values to range (inclusively) between 0 and 1, and in its linguistic form, imprecise concepts like “slightly”, “quite” and “very”. Specifically, it allows partial membership in a set.

Fuzzy Neural Networks (FNN): are Neural Networks that are enhanced with fuzzy logic capability such as using fuzzy data, fuzzy rules, sets and values.

Neuro-Fuzzy Systems (NFS): A neuro-fuzzy system is a fuzzy system that uses a learning algorithm derived from or inspired by neural network theory to determine its parameters (fuzzy sets and fuzzy rules) by processing data samples.

Self-Organizing Map (SOM): The self-organizing map is a subtype of artificial neural networks. It

is trained using unsupervised learning to produce low dimensional representation of the training samples while preserving the topological properties of the input space. The self-organizing map is a single layer feed-forward network where the output syntaxes are arranged in low dimensional (usually 2D or 3D) grid. Each input is connected to all output neurons. Attached to every neuron there is a weight vector with the same dimensionality as the input vectors. The number of input dimensions is usually a lot higher than the output grid dimension. SOMs are mainly used for dimensionality reduction rather than expansion.

Soft Computing: Soft Computing refers to a partnership of computational techniques in computer science, artificial intelligence, machine learning and some engineering disciplines, which attempt to study, model, and analyze complex phenomena. The principle partners at this juncture are fuzzy logic, neuron-computing, probabilistic reasoning, and genetic algorithms. Thus the principle of soft computing is to exploit the tolerance for imprecision, uncertainty, and partial truth to achieve tractability, robustness, low cost solution, and better rapport with reality.

Adaptive Technology and Its Applications

João José Neto

Universidade de São Paulo, Brazil

INTRODUCTION

Before the advent of software engineering, the lack of memory space in computers and the absence of established programming methodologies led early programmers to use self-modification as a regular coding strategy.

Although unavoidable and valuable for that class of software, solutions using self-modification proved inadequate while programs grew in size and complexity, and security and reliability became major requirements.

Software engineering, in the 70's, almost led to the vanishing of self-modifying software, whose occurrence was afterwards limited to small low-level machine-language programs with very special requirements.

Nevertheless, recent research developed in this area, and the modern needs for powerful and effective ways to represent and handle complex phenomena in high-technology computers are leading self-modification to be considered again as an implementation choice in several situations.

Artificial intelligence strongly contributed for this scenario by developing and applying non-conventional approaches, e.g. heuristics, knowledge representation and handling, inference methods, evolving software/hardware, genetic algorithms, neural networks, fuzzy systems, expert systems, machine learning, etc.

In this publication, another alternative is proposed for developing Artificial Intelligence applications: the use of adaptive devices, a special class of abstractions whose practical application in the solution of current problems is called Adaptive Technology.

The behavior of adaptive devices is defined by a dynamic set of rules. In this case, knowledge may be represented, stored and handled within that set of rules by adding and removing rules that represent the addition or elimination of the information they represent.

Because of the explicit way adopted for representing and acquiring knowledge, adaptivity provides a very simple abstraction for the implementation of artificial learning mechanisms: knowledge may be comfortably

gathered by inserting and removing rules, and handled by tracking the evolution of the set of rules and by interpreting the collected information as the representation of the knowledge encoded in the rule set.

MAIN FOCUS OF THIS ARTICLE

This article provides concepts and foundations on adaptivity and adaptive technology, gives a general formulation for adaptive abstractions in use and indicates their main applications.

It shows how rule-driven devices may turn into adaptive devices to be applied in learning systems modeling, and introduces a recently formulated kind of adaptive abstractions having adaptive subjacent devices. This novel feature may be valuable for implementing meta-learning, since it enables adaptive devices to change dynamically the way they modify their own set of defining rules.

A significant amount of information concerning adaptivity and related subjects may be found at the (LTA Web site).

BACKGROUND

This section summarizes the foundations of adaptivity and establishes a general formulation for adaptive rule-driven devices (Neto, 2001), non-adaptivity being the only restriction imposed to the subjacent device.

Some theoretical background is desirable for the study and research on adaptivity and Adaptive Technology: formal languages, grammars, automata, computation models, rule-driven abstractions and related subjects.

Nevertheless, either for programming purposes or for an initial contact with the theme, it may be unproblematic to catch the basics of adaptivity even having no prior expertise with computer-theoretical subjects.

In adaptive abstractions, adaptivity may be achieved by attaching adaptive actions to selected rules chosen

from the rule set defining some subjacent non-adaptive device.

Adaptive actions enable adaptive devices to dynamically change their behavior without external help, by modifying their own set of defining rules whenever their subjacent rule is executed.

For practical reasons, up to two adaptive actions are allowed: one to be performed prior to the execution of its underlying rule, and the other, after it.

An adaptive device behaves just as it were piecewise non-adaptive: starting with the configuration of its initial underlying device, it iterates the following two steps, until reaching some well-defined final configuration:

- While no adaptive action is executed, run the underlying device;
- Modify the set of rules defining the device by executing an adaptive action.

Rule-Driven Devices

A *rule-driven device* is any formal abstraction whose behavior is described by a rule set that maps each possible configuration of the device into a corresponding next one.

A device is *deterministic* when, for any configuration and any input, a single next configuration is possible. Otherwise, it is said *non-deterministic*.

Non-deterministic devices allow multiple valid possibilities for each move, and require backtracking, so deterministic equivalents are usually preferable in practice.

Assume that:

- D is some rule-driven device, defined as $D = (C, R, S, c_0, A)$.
- C is its set of possible configurations.
- $R \subseteq C \times (S \cup \{\varepsilon\}) \times C$ is the set of rules describing its behavior, where ε denotes empty stimulus, representing no events at all.
- S is its set of valid input stimuli.
- $c_0 \in C$ is its initial configuration.
- $A \subseteq C$ is its set of final configurations.

Let $c_i \Rightarrow^{(r)} c_{i+1}$ (for short, $c_i \Rightarrow c_{i+1}$) denote the application of some rule $r = (c_i, s, c_{i+1}) \in R$ to the current

configuration c_i in response to some input stimulus $s \in S \cup \{\varepsilon\}$, yielding its next configuration c_{i+1} .

Successive applications of rules in response to a stream $w \in S^*$ of input stimuli, starting from the initial configuration c_0 and leading to some final configuration

$c \in A$ is denoted $c_0 \Rightarrow_w^* c$ (The star postfix operator in the formulae denotes the Kleene closure: its preceding element may be re-instantiated or reapplied an arbitrary number of times).

We say that D defines a sentence w if, and only if,

$c_0 \Rightarrow_w^* c$ holds for some $c \in A$. The collection $L(D)$ of all such sentences is called the language defined by D :

$$L(D) = \{w \in S^* \mid c_0 \Rightarrow_w^* c, c \in A\}.$$

Adaptive (Rule-Driven) Devices

An adaptive rule-driven device $AD = (ND_0, AM)$ associates an initial subjacent rule-driven device $ND_0 = (C, NR_0, S, c_0, A)$, to some adaptive mechanism AM , that can dynamically change its behavior by modifying its defining rules.

That is accomplished by executing non-null adaptive actions chosen from a set AA of *adaptive actions*, which includes the *null adaptive action* a^0 .

A built-in counter t starts at 0 and is self-incremented upon any adaptive actions' execution. Let X_j denote the value of X after j executions of adaptive actions by AD .

Adaptive actions in AA call functions that map AD current set AR_t of adaptive rules into AR_{t+1} by inserting to and removing adaptive rules ar from AM .

Let \mathbf{AR} be the set of all possible sets of adaptive rules for AD . Any $a^k \in A$ maps the current set of rules $AR_t \in \mathbf{AR}$ into $AR_{t+1} \in \mathbf{AR}$:

$$a^k : \mathbf{AR} \rightarrow \mathbf{AR}$$

AM associates to each rule $nr^p \in NR$ of AD underlying device ND a pair of adaptive actions $ba^p, aa^p \in AA$:

$$AM \subseteq AA \times NR \times AA$$

Notation

When writing elementary adaptive actions, $?[ar]$, $+[ar]$ and $-[ar]$ respectively denote searching, inserting and eliminating adaptive rules that follow template ar .

Note that ar may contain references to parameters, variables and generators, in order to allow cross-referencing among elementary adaptive actions inside an adaptive function.

Given an underlying rule $nr^p \in NR$, we define an adaptive rule $ar^p \in AM$ as:

$$ar^p = (ba^p, nr^p, aa^p)$$

For each AD move, AM applies some ar^p in three steps:

- execution of adaptive action ba^p before applying the subjacent rule nr^p ;
- application of the underlying non-adaptive rule nr^p ;
- execution of adaptive action aa^p .

The following algorithm sketches the overall operation of AD :

- Initialize c_0, w ;
- If w is exhausted, go to 7 else get next event s_i ;
- For the current configuration c_i , determine the set CR of c_i -compatible rules;
 - if $CR = \emptyset$, reject w .
 - if $CR = \{(c_i, s, c')\}$, apply (c_i, s, c') as in steps 4-6, leading AD to $c_{i+1} = c'$.
 - if $CR = \{r^k = (c_i, s, c^k) \mid c^k \in C, k = 1, \dots, n, n > 1\}$, apply all rules r^k in parallel, as in steps 4-6, leading AD to c^1, c^2, \dots, c^n , respectively.
- If $ba^p = a^0$, go to 2, else apply first ba^p . If rule ar^p were removed by ba^p , go to 3 aborting ar^p , else AD reached an intermediate configuration, then go to 2.
- Apply nr^p to the current (intermediate) configuration, yielding a new intermediate configuration;

- Apply aa^p , yielding the next (stable) configuration for AD ; go to 2

- If some $c_{i+1} \in F$ was reached, then AD accepts w , otherwise AD rejects w ; stop.

Hierarchical Multi-Level Adaptive Devices

Let us define a more elaborated adaptive device by generalizing the definition above. Call non-adaptive devices *level-0 devices*; define *level-1 devices* those having subjacent level-0 devices, to each of whose rules a pair of level-1 adaptive actions are attached.

Let the subjacent device be some level- k adaptive device. One may construct a level- $(k+1)$ device attaching a pair of level- $(k+1)$ adaptive actions to each of its rules. This is the induction step for the definition of hierarchically structured multi-level adaptive devices.

Besides the set of rules defining the subjacent level- k device, for $k > 0$, adaptive functions' subjacent device performs at its own level, which may use level- $(k+1)$ adaptive actions to modify the behavior of level- k adaptive functions.

So, for $k > 0$, level- $(k+1)$ devices can change the way their subjacent level- k devices modify themselves. That also holds for $k = 1$, since even for $k = 0$ the (empty) set of adaptive functions still exists.

Notation

The absence of adaptive actions in non-adaptive rules nr is explicitly expressed by stating all level-0 rules r_0 in the form $(a^0 nr a^0)$. Therefore, level- k rules r_k take the general format $(b_k r_{k-1} a_k)$, with both b_k and a_k level- k adaptive actions for any adaptive level $k \geq 0$.

So, level- k adaptive devices have all their defining rules stated in the standard form

$$(b_k (b_{k-1} (\dots (b_1 (a^0(c, \sigma, c') a^0) a_1) \dots) a_{k-1}) a_k),$$

with

$$(b_{k-1} (\dots (b_1 (a^0(c, \sigma, c') a^0) a_1) \dots) a_{k-1})$$

representing one of the rules defining the subjacent level- $(k-1)$ adaptive device.

Hence, level- i adaptive actions can modify both the set of level- i adaptive rules and the set of elementary adaptive actions defining level- $(i - 1)$ adaptive functions.

A SIMPLE ILLUSTRATIVE EXAMPLE

In the following example, graphical notation is used for clarity and conciseness. When drawing automata, (as usual) circles represent states; double-line circles indicate final states; arrows indicate transitions; labels on the arrows indicate tokens consumed by the transition and (optionally) an associated adaptive action. When representing adaptive functions, automata fragments in brackets stand for a group of transitions to be added (+) or removed (-) when the adaptive action is applied.

Figure 1 shows the starting shape of an adaptive automaton that accepts $a^n b^{2n} c^{3n}$, $n \geq 0$. At state **1**, it includes a transition consuming **a**, which performs adaptive action $\mathcal{A}()$.

Figure 2 defines how $\mathcal{A}()$ operate:

Figure 1. Initial configuration of the illustrative adaptive automaton

Figure 2. Adaptive function $\mathcal{A}()$

- Using state **2** as reference, eliminate empty transitions using states **x** and **y**
- Add a sequence starting at **x**, with two transitions consuming **b**
- Append the sequence of two empty transitions sharing state **2**

Append a sequence with three transitions consuming **c**, ending at **y**.

Figure 3 shows the first two shape changes of this automaton after consuming the two first symbols **a** (at state **1**) in sentence $a^2 b^4 c^6$. In its last shape, the automaton trivially consumes the remaining $b^4 c^6$, and does not change any more.

There are many other examples of adaptive devices in the references. This almost trivial and intuitive case was shown here for illustration purposes only.

Knowledge Representation

The preceding example illustrates how adaptive devices use the set of rules as their only element for representing and handling knowledge.

A rule (here, a transition) may handle parametric information in its components (here, the transition's origin and destination states, the token labeling the transition, the adaptive function it calls, etc.).

Rules may be combined together in order to represent some non-elementary information (here, the sequences of transitions consuming tokens "b" and "c" keep track of the value of n in each particular sentence). This way, rules and their components may work and may be interpreted as low-level elements of knowledge.

Although being impossible to impose rules on how to represent and handle knowledge in systems repre-

Figure 3. Configurations of the adaptive automaton after executing $\mathcal{A}()$ once and twice

sented with adaptive devices, the details of the learning process may be chosen according to the particular needs of each system being modeled.

In practice, the learning behavior of an adaptive device may be identified and measured by tracking the progress of the set of rules during its operation and interpreting the dynamics of its changes.

In the above example, when transitions are added to the automaton by executing adaptive action $\mathcal{A}()$, one may interpret the length of the sequence of transitions consuming “b” (or “c”) as a manifestation of the knowledge that is being gathered by the adaptive automaton on the value of n (its exact value becomes available after the sub-string of tokens “a” is consumed).

FUTURE TRENDS

Adaptive abstractions represent a significant theoretical advance in Computer Science, by introducing and exploring powerful non-classical concepts such as: time-varying behavior, autonomously dynamic rule sets, multi-level hierarchy, static and dynamic adaptive actions.

Those concepts allow establishing a modeling style, proper for describing complex learning systems, for efficiently solving traditionally hard problems, for dealing with self-modifying learning methods, and for providing computer languages and environments for comfortable elaboration of quality programs with dynamically-variant behavior.

All those features are vital for conceiving, modeling, designing and implementing applications in Artificial Intelligence, which benefits from adaptivity while expressing traditionally difficult-to-describe Artificial Intelligence facts.

Listed below are features Adaptive Technology offers to several fields of Computation, especially to Artificial Intelligence-related ones, indicating their main impacts and applications.

- Adaptive Technology provides a true computation model, constructed around formal foundations. Most Artificial Intelligence techniques in use are very hard to express and follow since the connection between elements of the models and information they represent is often implicit, so their operation reasoning is difficult for a human to track and plan. Adaptive rule-driven devices concentrate all stored knowledge in their rules, and the whole logic that handles such information, in their adaptive actions. Such properties open for Artificial Intelligence the possibility to observe, understand and control adaptive-device-modeled phenomena. By following and interpreting how and why changes occur in the device set of rules, and by tracking semantics of adaptive actions, one can infer the reasoning of the model reactions to its input.
- Adaptive devices have enough processing power to model complex computations. In (Neto, 2000) some well-succeeded use cases are shown with

simple and efficient adaptive devices used instead of complex traditional formulations.

- Adaptive Devices are Turing Machine-equivalent computation models that may be used in the construction of single-notation full specifications of programming languages, including lexical, syntactical, context-dependent static-semantic issues, language built-in features such as arithmetic operations, libraries, semantics, code generation and optimization, run-time code interpreting, etc.
- Adaptive devices are well suited for representing complex languages, including idioms. Natural language particularly require several features to be expressed and handled, as word inflexions, orthography, multiple syntax forms, phrase ordering, ellipsis, permutation, ambiguities, anaphora and others. A few simple techniques allow adaptive devices to deal with such elements, strongly simplifying the effort of representing and processing them. Applications are wide, including machine translation, data mining, text-voice and voice-text conversion, etc.
- Computer art is another fascinating potential application of adaptive devices. Music and other artistic expressions are forms of human language. Given some language descriptions, computers can capture human skills and automatically generate interesting outputs. Well-succeeded experiments were carried out in the field of music, with excellent results (Bassetto, 1999).
- Decision-taking systems may use Adaptive Decision Tables and Trees for constructing intelligent systems that accept training patterns, learn how to classify them, and therefore, classify unknown patterns. Well-succeeded experiments include: classifying geometric patterns, decoding sign languages, locating patterns in images, generating diagnoses from symptoms and medical data, etc.
- Language inference uses Adaptive Devices to generate formal descriptions of languages from samples, by identifying and collecting structural information and generalizing on the evidence of repetitive or recursive constructs (Matsuno, 2006).
- Adaptive Devices can be used for learning purposes by storing as rules the gathered information on some monitored phenomenon. In educational

systems, the behavior of both students and trainers can be inferred and used to decide how to proceed.

- One can construct Adaptive Devices whose underlying abstraction is a computer language. Statements in such languages may be considered as rules defining behavior of a program. By attaching adaptive rules to statements, the program becomes self-modifiable. Adaptive languages are needed for adaptive applications to be expressed naturally. For adaptivity to become a true programming style, techniques and methods must be developed to construct good adaptive software, since adaptive applications developed so far were usually produced in strict ad-hoc way.

CONCLUSION

Adaptive Technology concerns techniques, methods and subjects referring to actual application of adaptivity.

Adaptive automata (Neto, 1994) were first proposed for practical representation of context-sensitive languages (Rubinstein, 1995). Adaptive grammars (Iwai, 2000) were employed as its generative counterpart (Burshteyn, 1990), (Christiansen, 1990), (Cabasino, 1992), (Shutt, 1993), (Jackson, 2006).

For specification and analysis of real time reactive systems, works were developed based on adaptive versions of statecharts (Almeida Jr., 1995), (Santos, 1997). An interesting confirmation of power and usability of adaptive devices for modeling complex systems (Neto, 2000) was the successful use of Adaptive Markov Chains in a computer music-generating device (Bassetto, 1999).

Adaptive Decision Tables (Neto, 2001) and Adaptive Decision Trees (Pistori, 2006) are nowadays being experimented in decision-taking applications.

Experiments have been reported that explore the potential of adaptive devices for constructing language inference systems (Neto, 1998), (Matsuno, 2006).

An important area in which adaptive devices shows its strength is the specification and processing of natural languages (Neto, 2003). Many other results are being achieved while representing syntactical context-dependencies of natural language.

Simulation and modeling of intelligent systems are other concrete applications of adaptive formalisms, as illustrated in the description of the control mechanism

of an intelligent autonomous vehicle which collects information from its environment and builds maps for navigation.

Many other applications for adaptive devices are possible in several fields.

KEY TERMS

Adaptivity: Property exhibited by structures that dynamically and autonomously change their own behavior in response to input stimuli.

Adaptive Computation Model: Turing-powerful abstraction that mimic the behavior of potentially self-modifying complex systems.

Adaptive Device: Structure with dynamic behavior, with some subjacent device and an adaptive mechanism.

Adaptive Functions and Adaptive Actions: Adaptive actions are calls to adaptive functions, which can determine changes to perform on its layer's rule set and on their immediately subjacent layer's adaptive functions.

Adaptive Mechanism: Alteration discipline associated to an adaptive device's rule set that change the behavior of its subjacent device by performing adaptive actions.

Adaptive Rule-Driven Device: Adaptive device whose behavior is defined by a dynamically changing set of rules, e.g. adaptive automata, adaptive grammars, etc.

Context-Dependency: Reinterpretation of terms, due to conditions occurring elsewhere in a sentence, e.g. agreement rules in English, type-checking in Pascal.

Context-Sensitive (-Dependent) Formalism: Abstraction capable of representing Chomsky type-1 or type-0 languages. Adaptive Automata and Adaptive Context-free Grammars are well suited to express such languages.

Hierarchical (Multilevel) Adaptive Device: Stratified adaptive structures whose involving layer's adaptive actions can modify both its own layer's rules and its underlying layer's adaptive functions.

Subjacent (or Underlying) Device: Any device used as basis to formulate adaptive devices. The innermost of a multilevel subjacent device must be non-adaptive.

Advanced Cellular Neural Networks Image Processing

A

J. Álvaro Fernández

University of Extremadura, Badajoz, Spain

INTRODUCTION

Since its introduction to the research community in 1988, the Cellular Neural Network (CNN) (Chua & Yang, 1988) paradigm has become a fruitful soil for engineers and physicists, producing over 1,000 published scientific papers and books in less than 20 years (Chua & Roska, 2002), mostly related to Digital Image Processing (DIP). This Artificial Neural Network (ANN) offers a remarkable ability of integrating complex computing processes into compact, real-time programmable analogic VLSI circuits as the ACE16k (Rodríguez *et al.*, 2004) and, more recently, into FPGA devices (Perko *et al.*, 2000).

CNN is the core of the revolutionary Analogic Cellular Computer (Roska *et al.*, 1999), a programmable system based on the so-called CNN Universal Machine (CNN-UM) (Roska & Chua, 1993). Analogic CNN computers mimic the anatomy and physiology of many sensory and processing biological organs (Chua & Roska, 2002).

This article continues the review started in this Encyclopaedia under the title *Basic Cellular Neural Network Image Processing*.

BACKGROUND

The standard CNN architecture consists of an $M \times N$ rectangular array of cells $C(i, j)$ with Cartesian coordinates (i, j) , $i = 1, 2, \dots, M$, $j = 1, 2, \dots, N$. Each cell or neuron $C(i, j)$ is bounded to a sphere of influence $S_r(i, j)$ of positive integer radius r , defined by:

$$S_r(i, j) = \left\{ C(k, l) \mid \max_{1 \leq k \leq M, 1 \leq l \leq N} \{|k - i|, |l - j|\} \leq r \right\} \quad (1)$$

This set is referred as a $(2r + 1) \times (2r + 1)$ neighbourhood. The parameter r controls the connectivity

of a cell. When $r > N/2$ and $M = N$, a fully connected CNN is obtained, a case that corresponds to the classic Hopfield ANN model.

The state equation of any cell $C(i, j)$ in the $M \times N$ array structure of the standard CNN may be described by:

$$C \frac{dz_{ij}(t)}{dt} = -\frac{1}{R} z_{ij}(t) + \sum_{C(k, l) \in S_r(i, j)} [A(i, j; k, l) \cdot y_{kl}(t) + B(i, j; k, l) \cdot x_{kl}] + I_{ij} \quad (2)$$

where C and R are values that control the transient response of the neuron circuit (just like an RC filter), I is generally a constant value that biases the state matrix $Z = \{z_{ij}\}$, and S_r is the local neighbourhood defined in (1), which controls the influence of the input data $X = \{x_{ij}\}$ and the network output $Y = \{y_{ij}\}$ for time t .

This means that both input and output planes interact with the state of a cell through the definition of a set of real-valued weights, $A(i, j; k, l)$ and $B(i, j; k, l)$, whose size is determined by r . The cloning templates A and B are called the feedback and feed-forward operators, respectively.

An isotropic CNN is typically defined with constant values for r, I, A and B , implying that for an input image X , a neuron $C(i, j)$ is provided for each pixel (i, j) , with constant weighted circuits defined by the feedback and feed-forward templates A and B . The neuron state value z_{ij} is adjusted with the bias parameter I , and passed as input to an output function of the form:

$$y_{ij} = \frac{1}{2} \left(|z_{ij}(t) + 1| - |z_{ij}(t) - 1| \right) \quad (3)$$

The vast majority of the templates defined in the CNN-UM template compendium of (Chua & Roska, 2002) are based on this isotropic scheme, using $r = 1$ and binary images in the input plane. If no feedback (i.e. $A = 0$) is used, then the CNN behaves as a convolution network, using B as a spatial filter, I as a threshold and the piecewise linear output (3) as a limiter. Thus,

virtually any spatial filter from DIP theory can be implemented on such a feed-forward CNN, ensuring binary output stability via the definition of a central feedback absolute value greater than 1.

ADVANCED CNN IMAGE PROCESSING

In this section, a description of more complex CNN models is performed in order to provide a deeper insight into CNN design, including multi-layer structures and nonlinear templates, and also to illustrate its powerful DIP capabilities.

Nonlinear Templates

A problem often addressed in DIP edge detection is the robustness against noise (Jain, 1989). In this sense, the EDGE CNN detector for grey-scale images given by

$$A = 2, B_{EDGE} = \begin{bmatrix} -1 & -1 & -1 \\ -1 & 8 & -1 \\ -1 & -1 & -1 \end{bmatrix}, I = -0.5 \quad (4)$$

is a typical example of a weak-against-noise filter, as a result of fixed linear feed-forward template combined with excitatory feedback. One way to provide the detector with more robustness against noise is via the definition of a nonlinear B template of the form:

$$B_{CONTOUR} = \begin{bmatrix} b & b & b \\ b & 0 & b \\ b & b & b \end{bmatrix} \text{ where } b = \begin{cases} 0.5 & |x_{ij} - x_{kl}| > th \\ -1 & |x_{ij} - x_{kl}| \leq th \end{cases} \quad (5)$$

This nonlinear template actually defines different coefficients for the surrounding pixels prior to perform the spatial filtering of the input image X . Thus, a CNN defined with nonlinear templates is generally dependent of X , and can not be treated as an isotropic model.

Just two values for the surrounding coefficients of B are allowed: one excitatory for greater than a threshold th luminance differences with the central pixel (i.e. edge pixels), and the other inhibitory, doubled in absolute value, for similar pixels, where th is usually set around

0.5. The feedback template $A = 2$ remains unchanged, but the value for the bias I must be chosen from the following analysis:

For a given state z_{ij} element, the contribution w_{ij} of the feed-forward nonlinear filter of (5) may be expressed as:

$$\begin{aligned} w_{ij} &= -1.0 \cdot p_s + 0.5 \cdot p_e \\ &= -(8 - p_e) + 0.5 \cdot p_e \\ &= -8 + 1.5 \cdot p_e \end{aligned} \quad (6)$$

where p_s is the number of similar pixels in the 3×3 neighbourhood and p_e the rest of edge pixels. E.g. if the central pixel has 8 edge neighbours, $w_{ij} = 12 - 8 = 4$, whereas if all its neighbours are similar to it, then $w_{ij} = -8$. Thus, a pixel will be selected as edge depending on the number of its edge neighbours, providing the possibility of noise reduction. For instance, edge detection for pixels with at least 3 edge neighbours forces that $I \in (4, 5)$.

The main result is that the inclusion of nonlinearities in the definition of B coefficients and, by extension, the pixel-wise definition of the main CNN parameters gives rise to more powerful and complex DIP filters (Chua & Roska, 1993).

Morphologic Operators

Mathematical Morphology is an important contributor to the DIP field. In the classic approach, every morphologic operator is based on a series of simple concepts from Set Theory. Moreover, all of them can be divided into combinations of two basic operators: erosion and dilation (Serra, 1982). Both operators take two pieces of data as input: the binary input image and the so-called structuring element, which is usually represented by a 3×3 template.

A pixel belongs to an object if it is active (i.e. its value is 1 or black), whereas the rest of pixels are classified as background, zero-valued elements. Basic morphologic operators are defined using only object pixels, marked as 1 in the structuring element. If a pixel is not used in the match, it is left blank. Both dilation and erosion operators may be defined by the structuring elements

$$\begin{array}{|c|c|c|} \hline 1 & 1 & 1 \\ \hline 1 & 1 & 1 \\ \hline 1 & 1 & 1 \\ \hline \end{array} \text{ and } \begin{array}{|c|c|c|} \hline & 1 & \\ \hline 1 & 1 & 1 \\ \hline & 1 & \\ \hline \end{array} \quad (7)$$

for 8 or 4-neighbour connectivity, respectively. In dilation, the structuring element is placed over each input pixel. If any of the 9 (or 5) pixels considered in (7) is active, then the output pixel will be also active (Jain, 1989). The erosion operator can be defined as the dual of dilation, i.e. a dilation performed over the background.

More complex morphologic operators are based on structuring elements that also contains background pixels. This is the case of the Hit and Miss Transform (HMT), a generalized morphologic operator used to identify certain local pixel configurations. For instance, the structuring elements defined by

$$\begin{array}{|c|c|c|} \hline 0 & 1 & \\ \hline 0 & 1 & 1 \\ \hline 0 & 0 & 0 \\ \hline \end{array} \text{ and } \begin{array}{|c|c|c|} \hline 1 & & 1 \\ \hline 0 & 1 & 0 \\ \hline 0 & 0 & 0 \\ \hline \end{array} \quad (8)$$

are used to find 90° convex corner object pixels within the image. A pixel will be selected as active in the output image if its local neighbourhood exactly matches with that defined by the structuring element. However, in order to calculate a full, non-orientated corner detector it will be necessary to perform 8 HMT, one for each rotated version of (8), OR-ing the 8 intermediate output images to obtain the final image (Fisher *et al.*, 2004).

In the CNN context, the HMT may be obtained in a straightforward manner by:

$$A = 2, \quad B_{HMT} : b_{ij} = \begin{cases} 1 & s_{ij} = 1 \\ 0 & \text{otherwise} \end{cases}, \quad I = 0.5 - p_s \quad (9)$$

where $S = \{s_{ij}\}$ is the structuring element and p_s is the total number of active pixels in it.

Since the input template B of the HTM CNN is defined via the structuring element S , and given that there are $2^9 = 512$ distinct 3×3 possible structuring elements, there will also be 512 different hit-and-miss erosions. For achieving the opposite result, i.e. hit-and-miss dilation, the threshold must be the opposite of that in (9) (Chua & Roska, 2002).

Dynamic Range Control CNN and Piecewise Linear Mappings

A

DIP techniques can be classified by the domain where they operate: the image or spatial domain or the transform domain (e.g. the Fourier domain). Spatial domain techniques are those who operate directly over the pixels within an image (e.g. its intensity level). A generic spatial operator can be defined by

$$Y(i, j) = T[X(i, j)]_s, \quad (10)$$

where X and Y are the input and output images, respectively, and T is a spatial operator defined over a neighbourhood S_r around each pixel $X(i, j)$, as defined in (1). Based on this neighbourhood, spatial operators can be grouped into two types: Single Point Processing Operators, also known as Mapping Operators, and Local Processing Operators, which can be defined by a spatial filter (i.e. 2D-discrete convolution) mask (Jain, 1989).

The simplest form of T is obtained when S_r is 1 pixel size. In this case, Y only depends of the intensity value of X for every pixel and T becomes an intensity level transformation function, or mapping, of the form

$$s = T(r) \quad (11)$$

where r and s are variables that represent grey level in X and Y , respectively.

According to this formulation, mappings can be achieved by direct application of a function over a range of input intensity levels. By properly choosing the form of T , a number of effects can be obtained, as the grey-level inversion, dynamic range compression or expansion (i.e. contrast enhancement), and threshold binarization for obtaining binary masks used in analysis and morphologic DIP.

A mapping is linear if its function T is also linear. Otherwise, T is not linear and the mapping is also non-linear. An example of nonlinear mapping is the CNN output function (3). It consists of three linear segments: two saturated levels, -1 and $+1$, and the central linear segment with unitary slope that connects them. This function is said to be piecewise linear and is closely related to the well-known sigmoid function utilized in the Hopfield ANN (Chua & Roska, 1993). It performs a mapping of intensity values stored in Z in the $[-1,$

+1] range. The bias I controls the average point of the input range, where the output function gives a zero-valued outcome.

Starting from the original CNN cell or neuron (1)-(3), a brief review of the Dynamic Range Control (DRC) CNN model first defined in (Fernández *et al.*, 2006) follows. This network is designed to perform a piecewise linear mapping T over X , with input range $[m-d, m+d]$ and output range $[a, b]$. Thus,

$$T[X(i, j)] = \begin{cases} a & -\infty < X(i, j) \leq m-d \\ \frac{b-a}{2d}(X(i, j)-m) + \frac{b+a}{2} & m-d < X(i, j) \leq m+d \\ b & m+d < X(i, j) < +\infty \end{cases} \quad (12)$$

In order to be able to implement this function in a multi-layer CNN, the following constraints must be met:

$$|b-a| \leq 2 \text{ and } d \leq 1 \quad (13)$$

A CNN cell which controls the desired input range can be defined with the following parameters:

$$A_1 = 0, B_1 = 1/d, I_1 = -m/d \quad (14)$$

This network performs a linear mapping between $[m-d, m+d]$ and $[-1, +1]$. Its output is the input of a second CNN whose parameters are:

$$A_2 = 0, B_2 = (b-a)/2, I_2 = (b+a)/2 \quad (15)$$

The output of this second network is exactly the mapping T defined in (12) bounded by the constraints of (13).

One of the simplest techniques used in grey-scale image contrast enhancement is contrast stretching or normalization. This technique maximizes the dynamic range of the intensity levels within the image from suitable estimates of the maximum and minimum intensity values (Fisher *et al.*, 2004). Thus, in the case of normalized grey-scale images, where the minimum (i.e. black) and maximum (i.e. white) intensity levels are represented by 0 and 1 values, respectively; if such an image with dynamic intensity range $[f, g] \subseteq [0, +1]$ is fed in the input of the 2-layer CNN defined by (14) and (15), the following parameters will achieve the desired linear dynamic range maximization:

$$a = 0, b = 1, m = (g+f)/2, d = (g-f)/2 \quad (16)$$

The DRC network can be easily applied to a first order piecewise polynomial approximation of nonlinear, continuous mappings. One of the valid possibilities is the multi-layer DRC CNN implementation of error-controlled Chebyshev polynomials, as described in (Fernández *et al.*, 2006). The possible mappings include, among many others, the absolute value, logarithmic, exponential, radial basis and integer and real-valued power functions.

FUTURE TRENDS

There is a continuous quest by engineers and specialists: compete with and imitate nature, especially some “smart” animals. Vision is one particular area which computer engineers are interested in. In this context, the so-called Bionic Eye (Werblin *et al.*, 1995) embedded in the CNN-UM architecture is ideal for implementing many spatio-temporal neuromorphic models.

With its powerful image processing toolbox and a compact VLSI implementation (Rodríguez *et al.*, 2004), the CNN-UM can be used to program or mimic different models of retinas and even combinations of them. Moreover, it can combine biologically based models, biologically inspired models, and analogic artificial image processing algorithms. This combination will surely bring a broader kind of applications and developments.

CONCLUSION

A number of other advances in the definition and characterization of CNN have been researched in the past decade. This includes the definition of methods for designing and implementing larger than 3×3 neighbourhoods in the CNN-UM (Kék & Zarándy, 1998), the CNN implementation of some image compression techniques (Venetianer *et al.*, 1995) or the design of a CNN-based Fast Fourier Transform algorithm over analogic signals (Perko *et al.*, 1998), between many others.

In this article, a general review of the main properties and features of the Cellular Neural Network model has been addressed focusing on its DIP applications. The

CNN is now a fundamental and powerful toolkit for real-time nonlinear image processing tasks, mainly due to its versatile programmability, which has powered its hardware development for visual sensing applications (Roska *et al.*, 1999).

KEY TERMS

Bionics: The application of methods and systems found in nature to the study and design of engineering systems. The word seems to have been formed from “biology” and “electronics” and was first used by J. E. Steele in 1958.

Chebyshev Polynomial: An important type of polynomials used in data interpolation, providing the best approximation of a continuous function under the maximum norm.

Dynamic Range: A term used to describe the ratio between the smallest and largest possible values of a variable quantity.

FPGA: Acronym that stands for Field-Programmable Gate Array, a semiconductor device invented

in 1984 by R. Freeman that contains programmable interfaces and logic components called “logic blocks” used to perform the function of basic logic gates (e.g. XOR) or more complex combination functions such as decoders.

Piecewise Linear Function: A function $f(x)$ that can be split into a number of linear segments, each of which is defined for a non-overlapping interval of x .

Spatial Convolution: A term used to identify the linear combination of a series of discrete 2D data (a digital image) with a few coefficients or weights. In the Fourier theory, a convolution in space is equivalent to (spatial) frequency filtering.

Template: Also known as kernel, or convolution kernel, is the set of coefficients used to perform a spatial filter operation over a digital image via the spatial convolution operator.

VLSI: Acronym that stands for Very Large Scale Integration. It is the process of creating integrated circuits by combining thousands (nowadays hundreds of millions) of transistor-based circuits into a single chip. A typical VLSI device is the microprocessor.

Agent-Based Intelligent System Modeling

INTRODUCTION

An intelligent system is a system that has, similar to a living organism, a coherent set of components and subsystems working together to engage in goal-driven activities. In general, an intelligent system is able to sense and respond to the changing environment; gather and store information in its memory; learn from earlier experiences; adapt its behaviors to meet new challenges; and achieve its pre-determined or evolving objectives. The system may start with a set of predefined stimulus-response rules. Those rules may be revised and improved through learning. Anytime the system encounters a situation, it evaluates and selects the most appropriate rules from its memory to act upon.

Most human organizations such as nations, governments, universities, and business firms, can be considered as intelligent systems. In recent years, researchers have developed frameworks for building organizations around intelligence, as opposed to traditional approaches that focus on products, processes, or functions (e.g., Liang, 2002; Gupta and Sharma, 2004). Today's organizations must go beyond traditional goals of efficiency and effectiveness; they need to have organizational intelligence in order to adapt and survive in a continuously changing environment (Liebowitz, 1999). The intelligent behaviors of those organizations include monitoring of operations, listening and responding to stakeholders, watching the markets, gathering and analyzing data, creating and disseminating knowledge, learning, and effective decision making.

Modeling intelligent systems has been a challenge for researchers. Intelligent systems, in particular, those involve multiple intelligent players, are complex

systems where system dynamics does not follow clearly defined rules. Traditional system dynamics approaches or statistical modeling approaches rely on rather restrictive assumptions such as homogeneity of individuals in the system. Many complex systems have components or units which are also complex systems. This fact has significantly increased the difficulty of modeling intelligent systems. Agent-based modeling of complex systems such as ecological systems, stock market, and disaster recovery has recently garnered significant research interest from a wide spectrum of fields from politics, economics, sociology, mathematics, computer science, management, to information systems. Agent-based modeling is well suited for intelligent systems research as it offers a platform to study systems behavior based on individual actions and interactions. In the following, we present the concepts and illustrate how intelligent agents can be used in modeling intelligent systems.

We start with basic concepts of intelligent agents. Then we define agent-based modeling (ABM) and discuss strengths and weaknesses of ABM. The next section applies ABM to intelligent system modeling. We use an example of technology diffusion for illustration. Research issues and directions are discussed next, followed by conclusions.

INTELLIGENT AGENT

Intelligent agents, also known as software agents, are computer applications that autonomously sense and respond to environment in the pursuit of certain designed objectives (Wooldridge and Jennings, 1995). Intelligent agents exhibit some level of intelligence. They can be

used to assist the user in performing non-repetitive tasks, such as seeking information, shopping, scheduling, monitoring, control, negotiation, and bargaining.

Intelligent agents may come in various shapes and forms such as knowbots, softbots, taskbots, personal agents, shopbots, information agents, etc. No matter what shape or form they have, intelligent agents exhibit one or more of the following characteristics:

- **Autonomous:** Being able to exercise control over their own actions.
- **Adaptive/Learning:** Being able to learn and adapt to their external environment.
- **Social:** Being able to communicate, bargain, collaborate, and compete with other agents on behalf of their masters (users).
- **Mobile:** Being able to migrate themselves from one machine/system to another in a network, such as the Web.
- **Goal-oriented:** Being able to act in accordance with built-in goals and objectives.
- **Communicative:** Being able to communicate with people or other agents through protocols such as agent communication language (ACL).
- **Intelligent:** Being able to exhibit intelligent behavior such as reasoning, generalizing, learning, dealing with uncertainty, using heuristics, and natural language processing.

AGENT-BASED MODELING

Using intelligent agents and their actions and interactions in a given environment to simulate the complex dynamics of a system is referred to as agent-based modeling. ABM research is closely related to the research in complex systems, emergence, computational sociology, multi agent systems, evolutionary programming, and intelligent organizations. In ABM, system behavior results from individual behaviors and collective behaviors of the agents. Researchers of ABM are interested in how macro phenomena are emerging from micro level behaviors among a heterogeneous set of interacting agents (Holland, 1992). Every agent has its attributes and its behavior rules. When agents encounter in the agent society, each agent individually assesses the situation and makes decisions on the basis of its behavior rules. In general, individual agents do

not have global awareness in the multi-agent system.

Agent-based modeling allows a researcher to set different parameters and behavior rules of individual agents. The modeler makes assumptions that are most relevant to the situation at hand, and then watches phenomena emerge from the interactions of the agents. Various hypotheses can be tested by changing agent parameters and rules. The emergent collective pattern of the agent society often leads to results that may not have been predicated.

One of the main advantages of ABM over traditional mathematical equation based modeling is the ability to model individual styles and attributes, rather than assuming homogeneity of the whole population. Traditional models based on analytical techniques often become intractable as the systems reach real-world level of complexity. ABM is particularly suitable for studying system dynamics that are generated from interactions of heterogeneous individuals. In recent years, ABM has been used in studying many real world systems, such as stock markets (Castiglione 2000), group selection (Pepper 2000), and workflow and information diffusion (Neri 2004). Bonabeau (2002) presents a good summary of ABM methodology and the scenarios where ABM is appropriate.

ABM is, however, not immune from criticism. Per Bonabeau (2002), “an agent-based model will only be as accurate as the assumptions and data that went into it, but even approximate simulations can be very valuable”. It has also been observed that ABM relies on simplified models of rule-based human behavior that often fail to take into consideration the complexity of human cognition. Besides, it suffers from “unwrapping” problem as the solution is built into the program and thus prevents occurrence of new or unexpected events (Macy, 2002).

ABM FOR INTELLIGENT SYSTEMS

An intelligent system is a system that can sense and respond to its environment in pursuing its goals and objectives. It can learn and adapt based on past experience. Examples of intelligent systems include, but not limited to, the following: biological life such as human beings, artificial intelligence applications, robots, organizations, nations, projects, and social movements.

Walter Fritz (1997) suggests that the key components of an intelligent system include objectives, senses, concepts, growth of a concept, present situation, response rules, mental methods, selection, actions, reinforcement, memory and forgetting, sleeping, and patterns (high level concepts). It is apparent that traditional analytical modeling techniques are not able to model many of the components of intelligent systems, let alone the complete system dynamics. However, ABM lends itself well to such a task. All those components can be models as agents (albeit some in abstract sense). An intelligent system is thus made of inter-related and interactive agents. ABM is especially suitable for intelligent systems consist of a large number of heterogeneous participants, such as a human organization.

Modeling Processes

Agent-based modeling for intelligent systems starts with a thorough analysis of the intelligent systems. Since the system under consideration may exhibit complex behaviors, we need to identify one or a few key features to focus on. Given a scenario of the target intelligent system, we first establish a set of objectives that we aim to achieve via the simulation of the agent-based representation of the intelligent system. The objectives of the research can be expressed as a set of questions to which we seek answers (Doran, 2006).

A conceptual model is created to lay out the requirements for achieving the objectives. This includes defining the entities, such as agents, environment, resources, processes, and relationships. The conceptual modeling phase answers the question of what—what are needed. The design model determines how the requirements can be implemented, including defining the features and relevant behaviors of the agents (Brown, 2006).

Depending on the goals of a particular research, a model may involve the use of designed or empirically grounded agents. Designed agents are those endowed with characteristics and behaviors that represent conditions for testing specific hypotheses about the intelligent systems. When the agents are empirically grounded, they are used to represent real world entities, such as individuals or processes in an organization. Empirically grounded agents are feasible only when data about the real world entities are available. Similarly, the environment within which the agents act can be

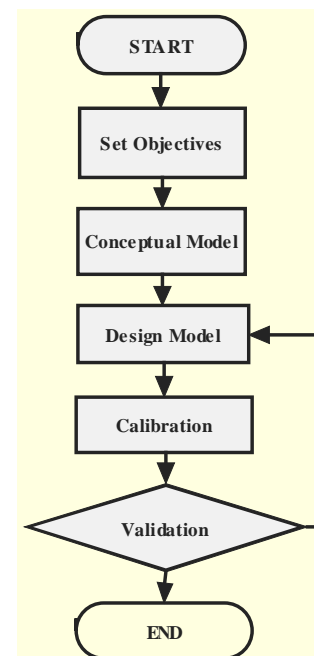

designed or empirically grounded. In practice, a study may start with simple models, often with designed agents and environments, to explore certain specific dynamics of the system.

The design model is refined through the calibration process, in which design parameters are modified to improve the desired characteristics of the model. The final step in the modeling process is validation where we check the agent individual behavior, interactions, and emergent properties of the system against expected design features. Validation usually involves comparison of model outcomes, often at the macro-level, with comparable outcomes in the real world (Midgley, et al., 2007). Figure 1 shows the complete modeling process. A general tutorial on ABM is given by Macal and North (2005).

ABM for Innovation Diffusion

We present an example of using agent-based intelligent system modeling for studying the acceptance and diffusion of innovative ideas or technology. Diffusion of innovation has been studied extensively over the last few decades (Rogers, 1995). However, traditional research in innovation diffusion has been grounded on case based analysis and analytical systems modeling

Figure 1. Agent-based modeling process

(e.g., using differential and difference equations). Agent-based modeling for diffusion of innovation is relatively new. Our example is adopted from a model created by Michael Samuels (2007), implemented with a popular agent modeling system—NetLogo.

The objective of innovation diffusion modeling is to answer questions such as how an idea or technology is adopted in a population, how different people (e.g., innovators, early adopters, and change agents) influence each other, and under what condition an innovation will be accepted or rejected by the population. In the conceptual modeling, we identify various factors that influence an individual's propensity for adopting the innovation. Those factors are broadly divided into two categories: internal influences (e.g., word-of-mouth) and external influences (e.g. mass media). Any factor that exerts its influence through individual contact is considered internal influence.

Individuals in the target population are divided into four groups: *adopter*, *potential* (adopter), *change agent*, and *disrupter*. *Adopters* are those who have adopted the innovation, while *potentials* are those who have certain likelihood to adopt the innovation. *Change agents* are the champions of the innovation. They are very knowledgeable and enthusiastic about the innovation, and often play a critical role in facilitating its- diffusion. *Disrupters* are those who play an opposite role of *change agents*. They are against the current innovation, oftentimes because they favor an even

newer and perceived better innovation. The four groups of agents and their relationships are depicted in Figure 2. It is common, although not necessary, to assume that those four groups make up the entire population.

In a traditional diffusion model, such as the Bass model (Bass, 1996), the diffusion rate depends only on the number of adopters (and potential adopters, given fixed population size). Characteristics of individuals in the population are ignored. Even in those models where it is assumed that potential adopters have varying threshold for adopting an innovation (Abrahamson and Rosenkopf, 1997), the individuality is very limited. However, in agent-based modeling, the types of individuals and individual characteristics are essentially unbounded. For example, we can divide easily adopters into innovators, early adopters, and late adopters, etc. If necessary, various demographic and social-economic features can be bestowed to individual agents. Furthermore, both internal influence and external influence can be further attributed to more specific causes. For example, internal influence through social networks can be divided into traditional social networks that consists friends and acquaintances and virtual social networks formed online. Table 1 lists typical factors that affect the propensity of adopting an innovation.

An initial study of innovation diffusion, such as the one in Michael Samuels (2007), can simply aggregate all internal influences into “word-of-mouth” and all external influences into mass media. Each potential adopter's tendency of converting to an adopter is influenced by chance encounter with other agents. If a potential adopter meets a change agent, who is an avid promoter of the innovation, he would become more knowledgeable about the advantages of the innovation, and more likely to adopt. An encounter with a disrupter

Figure 2. Agents and influences

Table 1. Typical internal and external influences

| Internal influence | External influence |
|----------------------------------|--------------------------------|
| Word-of-mouth | Newspapers |
| Telephone | Television |
| Email | Laws, policies and regulations |
| Instant message | Culture |
| Chat | Internet/Web |
| Blog | Online communities |
| Social networks (online/offline) | RSS |

creates the opposite effect, as a disrupter favors a different type of innovation.

In order for the simulated model to accurately reflect a real-world situation, the model structure and parameter values should be carefully selected. For example, we need to decide how much influence each encounter will result; what is the probability of encountering a change agent or a disrupter; how much influence is coming from the mass media, etc. We can get these values through surveys, statistical analysis of empirical data, or experiments specifically designed to elicit data from real world situations.

TRENDS AND RESEARCH ISSUES

As illustrated through the example of modeling the diffusion of innovation in an organization, industry, or society, agent-based modeling can be used to model the adaptation of intelligent systems that consist of intelligent individuals. As most intelligent systems are complex in both structure and system dynamics, traditional modeling tools that require too many unrealistic assumptions have become less effective in modeling intelligent systems. In recent years, agent-based modeling has found a wide spectrum of applications such as in business strategic solutions, supply chain management, stock markets, power economy, social evolution, military operations, security, and ecology (North and Macal, 2007). As ABM tools and resources become more accessible, research and applications of agent-based intelligent system modeling are expected to increase in the near future.

Some challenges remain, though. Using ABM to model intelligent systems is a research area that draws theories from other fields, such as economics, psychology, sociology, etc., but without its own well established theoretic foundation. ABM has four key assumptions (Macy and Willer, 2002): Agents act locally with little or no central authority; agents are interdependent; agents follow simple rules, and agents are adaptive. However, some of those assumptions may not be applicable to intelligent system modeling. Central authorities, or central authoritative information such as mass media in the innovation diffusion example, may play an important role in intelligent organizations. Not all agents are alike in an intelligent system. Some may be independent, non-adaptive, or following complex behavior rules.

ABM uses a “bottom-up” approach, creating emergent behaviors of an intelligent system through “actors” rather than “factors”. However, macro-level factors have direct impact on macro behaviors of the system. Macy and Willer (2002) suggest that bringing those macro-level factors back will make agent-based modeling more effective, especially in intelligent systems such as social organizations.

Recent intelligent systems research has developed the concept of integrating human and machine-based data, knowledge, and intelligence. Kirn (1996) postulates that the organization of the 21st century will involve artificial agents based system highly intertwined with human intelligence of the organization. Thus, a new challenge for agent-based intelligent system modeling is to develop models that account for interaction, aggregation, and coordination of intelligent agent and human agents. The ABM will represent not only the human players in an intelligent system, but also the intelligent agents that are developed in real-world applications in those systems.

CONCLUSION

Modeling intelligent systems involving multiple intelligent players has been difficult using traditional approaches. We have reviewed recent development in agent-based modeling and suggest agent-based modeling is well suited for studying intelligent systems, especially those systems with sophisticated and heterogeneous participants. Agent-based modeling allows us to model system behaviors based on the actions and interactions of individuals in the system. Although most ABM research focuses on local rules and behaviors, it is possible that we integrate global influences in the models. ABM represents a novel approach to model intelligent systems. Combined with traditional modeling approaches (for example, micro-level simulation as proposed in MoSeS), ABM offers researchers a promising tool to solve complex and practical problems and to broaden research endeavors (Wu, 2007).

Lester Ingber Research, USA

INTRODUCTION

A briefing (Allen, 2004) demonstrates the breadth and depth complexity required to address real diplomatic, information, military, economic (DIME) factors for the propagation/evolution of ideas through defined populations. An open mind would conclude that it is possible that multiple approaches may be required for multiple decision makers in multiple scenarios. However, it is in the interests of multiple decision-makers to as much as possible rely on the same generic model for actual computations. Many users would have to trust that the coded model is faithful to process their inputs.

Similar to DIME scenarios, sophisticated competitive marketing requires assessments of responses of populations to new products.

Many large financial institutions are now trading at speeds barely limited by the speed of light. They co-locate their servers close to exchange floors to be able to turn quotes into orders to be executed within msecs. Clearly, trading at these speeds require automated algorithms for processing and making decisions. These algorithms are based on "technical" information derived from price, volume and quote (Level II) information. The next big hurdle to automated trading is to turn "fundamental" information into technical indicators, e.g., to include new political and economic news into such algorithms.

BACKGROUND

The concept of "memes" is an example of an approach to deal with DIME factors (Situngkir, 2004). The meme approach, using a reductionist philosophy of evolution among genes, is reasonably contrasted to approaches emphasizing the need to include relatively global influences of evolution (Thurtle, 2006).

There are multiple other alternative works being conducted world-wide that must be at least kept in mind while developing and testing models of evolution/propagation of ideas in defined populations: A

study on a simple algebraic model of opinion formation concluded that the only final opinions are extremal ones (Aletti et al., 2006). A study of the influence on chaos on opinion formation, using a simple algebraic model, concluded that contrarian opinion could persist and be crucial in close elections, albeit the authors were careful to note that most real populations probably do not support chaos (Borghesi & Galam, 2006). A limited review of work in social networks illustrates that there are about as many phenomena to be explored as there are disciplines ready to apply their network models (Sen, 2006).

Statistical Mechanics of Neocortical Interactions (SMNI)

A class of AI algorithms that has not yet been developed in this context takes advantage of information known about real neocortex. It seems appropriate to base an approach for propagation of ideas on the only system so far demonstrated to develop and nurture ideas, i.e., the neocortical brain. A statistical mechanical model of neocortical interactions, developed by the author and tested successfully in describing short-term memory (STM) and electroencephalography (EEG) indicators, is the proposed bottom-up model. Ideas by Statistical Mechanics (ISM) is a generic program to model evolution and propagation of ideas/patterns throughout populations subjected to endogenous and exogenous interactions (Ingber, 2006). ISM develops subsets of macrocolumnar activity of multivariate stochastic descriptions of defined populations, with macrocolumns defined by their local parameters within specific regions and with parameterized endogenous inter-regional and exogenous external connectivities. Parameters of subsets of macrocolumns will be fit to patterns representing ideas. Parameters of external and inter-regional interactions will be determined that promote or inhibit the spread of these ideas. Fitting such nonlinear systems requires the use of sampling techniques.

The author's approach uses guidance from his statistical mechanics of neocortical interactions (SMNI),

developed in a series of about 30 published papers from 1981-2001 (Ingber, 1983; Ingber, 1985; Ingber, 1992; Ingber, 1994; Ingber, 1995; Ingber, 1997). These papers also address long-standing issues of information measured by electroencephalography (EEG) as arising from bottom-up local interactions of clusters of thousands to tens of thousands of neurons interacting via short-ranged fibers), or top-down influences of global interactions (mediated by long-ranged myelinated fibers). SMNI does this by including both local and global interactions as being necessary to develop neocortical circuitry.

Statistical Mechanics of Financial Markets (SMFM)

Tools of financial risk management, developed to process correlated multivariate systems with differing non-Gaussian distributions using modern copula analysis enables bona fide correlations and uncertainties of success and failure to be calculated. Since 1984, the author has published about 20 papers developing a Statistical Mechanics of Financial Markets (SMFM), many available at <http://www.ingber.com>. These are relevant to ISM, to properly deal with real-world distributions that arise in such varied contexts.

Gaussian copulas are developed in a project Trading in Risk Dimensions (TRD) (Ingber, 2006). Other copula distributions are possible, e.g., Student-t distributions. These alternative distributions can be quite slow because inverse transformations typically are not as quick as for the present distribution. Copulas are cited as an important component of risk management not yet widely used by risk management practitioners (Blanco, 2005).

Sampling Tools

Computational approaches developed to process different approaches to modeling phenomena must not be confused with the models of these phenomena. For example, the meme approach lends it self well to a computational scheme in the spirit of genetic algorithms (GA). The cost/objective function that describes the phenomena of course could be processed by any other sampling technique such as simulated annealing (SA). One comparison (Ingber & Rosen, 1992) demonstrated the superiority of SA over GA on cost/objective functions used in a GA database. That study used Very Fast

Simulated Annealing (VFSR), created by the author for military simulation studies (Ingber, 1989), which has evolved into Adaptive Simulated Annealing (ASA) (Ingber, 1993). However, it is the author's experience that the Art and Science of sampling complex systems requires tuning expertise of the researcher as well as good codes, and GA or SA likely would do as well on cost functions for this study.

If there are not analytic or relatively standard math functions for the transformations required, then these transformations must be performed explicitly numerically in code such as TRD. Then, the ASA_PARALLEL_OPTIONS already existing in ASA (developed as part of the 1994 National Science Foundation Parallelizing ASA and PATHINT Project (PAPP)) would be very useful to speed up real time calculations (Ingber, 1993). Below, only a few topics relevant to ISM are discussed. More details are in a previous report (Ingber, 2006).

SMNI AND SMFM APPLIED TO ARTIFICIAL INTELLIGENCE

Neocortex has evolved to use minicolumns of neurons interacting via short-ranged interactions in macrocolumns, and interacting via long-ranged interactions across regions of macrocolumns. This common architecture processes patterns of information within and among different regions of sensory, motor, associative cortex, etc. Therefore, the premise of this approach is that this is a good model to describe and analyze evolution/propagation of ideas among defined populations.

Relevant to this study is that a spatial-temporal lattice-field short-time conditional multiplicative-noise (nonlinear in drifts and diffusions) multivariate Gaussian-Markovian probability distribution is developed faithful to neocortical function/physiology. Such probability distributions are a basic input into the approach used here. The SMNI model was the first physical application of a nonlinear multivariate calculus developed by other mathematical physicists in the late 1970s to define a statistical mechanics of multivariate nonlinear nonequilibrium systems (Graham, 1977; Langouche et al., 1982).

SMNI Tests on STM and EEG

SMNI builds from synaptic interactions to minicolumnar, macrocolumnar, and regional interactions in neocortex. Since 1981, a series of SMNI papers has been developed model columns and regions of neocortex, spanning mm to cm of tissue. Most of these papers have dealt explicitly with calculating properties of STM and scalp EEG in order to test the basic formulation of this approach (Ingber, 1983; Ingber, 1985; Ingber & Nunez, 1995).

The SMNI modeling of local mesocolumnar interactions (convergence and divergence between minicolumnar and macrocolumnar interactions) was tested on STM phenomena. The SMNI modeling of macrocolumnar interactions across regions was tested on EEG phenomena.

SMNI Description of STM

SMNI studies have detailed that maximal numbers of attractors lie within the physical firing space of both excitatory and inhibitory minicolumnar firings, consistent with experimentally observed capacities of auditory and visual STM, when a "centering" mechanism is enforced by shifting background noise in synaptic interactions, consistent with experimental observations under conditions of selective attention (Ingber, 1985; Ingber, 1994).

These calculations were further supported by high-resolution evolution of the short-time conditional-probability propagator using PATHINT (Ingber & Nunez, 1995). SMNI correctly calculated the stability and duration of STM, the primacy versus recency rule,

Figure 1. Illustrated are three biophysical scales of neocortical interactions: (a)-(a)-(a') microscopic neurons; (b)-(b') mesocolumnar domains; (c)-(c') macroscopic regions (Ingber, 1983). SMNI has developed appropriate conditional probability distributions at each level, aggregating up from the smallest levels of interactions. In (a*) synaptic inter-neuronal interactions, averaged over by mesocolumns, are phenomenologically described by the mean and variance of a distribution Ψ . Similarly, in (a) intraneuronal transmissions are phenomenologically described by the mean and variance of Γ . Mesocolumnar averaged excitatory (E) and inhibitory (I) neuronal firings M are represented in (a'). In (b) the vertical organization of minicolumns is sketched together with their horizontal stratification, yielding a physiological entity, the mesocolumn. In (b') the overlap of interacting mesocolumns at locations r and r' from times t and $t + \tau$ is sketched. In (c) macroscopic regions of neocortex are depicted as arising from many mesocolumnar domains. (c') sketches how regions may be coupled by long-ranged interactions.*

random access to memories within tenths of a second as observed, and the observed 7 ± 2 capacity rule of auditory memory and the observed 4 ± 2 capacity rule of visual memory.

SMNI also calculates how STM patterns (e.g., from a given region or even aggregated from multiple regions) may be encoded by dynamic modification of synaptic parameters (within experimentally observed ranges) into long-term memory patterns (LTM) (Ingber, 1983).

SMNI Description of EEG

Using the power of this formal structure, sets of EEG and evoked potential data from a separate NIH study, collected to investigate genetic predispositions to alcoholism, were fitted to an SMNI model on a lattice of regional electrodes to extract brain "signatures" of STM (Ingber, 1997). Each electrode site was represented by an SMNI distribution of independent stochastic macrocolumnar-scaled firing variables, interconnected by long-ranged circuitry with delays appropriate to long-fiber communication in neocortex. The global optimization algorithm ASA was used to perform maximum likelihood fits of Lagrangians defined by path integrals of multivariate conditional probabilities. Canonical momenta indicators (CMI) were thereby derived for individual's EEG data. The CMI give better signal recognition than the raw data, and were used to advantage as correlates of behavioral states. In-sample data was used for training (Ingber, 1997), and out-of-sample data was used for testing these fits. The architecture of ISM is modeled using scales similar to those used for local STM and global EEG connectivity.

Generic Mesoscopic Neural Networks

SMNI was applied to a parallelized generic mesoscopic neural networks (MNN) (Ingber, 1992), adding computational power to a similar paradigm proposed for target recognition.

"Learning" takes place by presenting the MNN with data, and parametrizing the data in terms of the firings, or multivariate firings. The "weights," or coefficients of functions of firings appearing in the drifts and diffusions, are fit to incoming data, considering the joint "effective" Lagrangian (including the logarithm of the prefactor in the probability distribution) as a dynamic

Figure 2. Scales of interactions among minicolumns are represented, within macrocolumns, across macrocolumns, and across regions of macrocolumns

cost function. This program of fitting coefficients in Lagrangian uses methods of ASA. "Prediction" takes advantage of a mathematically equivalent representation of the Lagrangian path-integral algorithm, i.e., a set of coupled Langevin rate-equations. A coarse deterministic estimate to "predict" the evolution can be applied using the most probable path, but PATHINT has been used. PATHINT, even when parallelized, typically can be too slow for "predicting" evolution of these systems. However, PATHTREE is much faster.

Architecture for Selected ISM Model

The primary objective is to deliver a computer model that contains the following features: (1) A multivariable space will be defined to accommodate populations. (2) A cost function over the population variables in (1) will be defined to explicitly define a pattern that can be identified as an Idea. A very important issue is for this project is to develop cost functions, not only how to fit or process them. (3) Subsets of the population will be used to fit parameters — e.g., coefficients of variables, connectivities to patterns, etc. — to an Idea, using the cost function in (2). (4) Connectivity of the population in (3) will be made to the rest of the population. Investigations will be made to determine what endogenous connectivity is required to stop or promote the propagation of the Idea into other regions of the population. (5) External forces, e.g., acting only on specific regions of the population, will be introduced, to determine how these exogenous forces may stop or promote the propagation of an Idea.

Application of SMNI Model

The approach is to develop subsets of Ideas/macrocolumnar activity of multivariate stochastic descriptions of

defined populations (of a reasonable but small population samples, e.g., of 100-1000), with macrocolumns defined by their local parameters within specific regions (larger samples of populations) and with parameterized long-ranged inter-regional and external connectivities. Parameters of a given subset of macrocolumns will be fit using ASA to patterns representing Ideas, akin to acquiring hard-wired long-term (LTM) patterns. Parameters of external and inter-regional interactions will be determined that promote or inhibit the spread of these Ideas, by determining the degree of fits and overlaps of probability distributions relative to the seeded macrocolumns.

That is, the same Ideas/patterns may be represented in other than the seeded macrocolumns by local confluence of macrocolumnar and long-ranged firings, akin to STM, or by different hard-wired parameter LTM sets that can support the same local firings in other regions (possible in nonlinear systems). SMNI also calculates how STM can be dynamically encoded into LTM (Ingber, 1983).

Small populations in regions will be sampled to determine if the propagated Idea(s) exists in its pattern space where it did exist prior to its interactions with the seeded population. SMNI derives nonlinear functions as arguments of probability distributions, leading to multiple STM, e.g., 7 ± 2 for auditory memory capacity. Some investigation will be made into nonlinear functional forms other than those derived for SMNI, e.g., to have capacities of tens or hundreds of patterns for ISM.

Application of TRD Analysis

This approach includes application of methods of portfolio risk analysis to such statistical systems, correcting two kinds of errors committed in multivariate risk analyses: (E1) Although the distributions of variables being considered are not Gaussian (or not tested to see how close they are to Gaussian), standard statistical calculations appropriate only to Gaussian distributions are employed. (E2) Either correlations among the variables are ignored, or the mistakes committed in (E1) — incorrectly assuming variables are Gaussian — are compounded by calculating correlations as if all variables were Gaussian.

It should be understood that any sampling algorithm processing a huge number of states can find many multiple optima. ASA's MULTI_MIN OPTIONS are

used to save multiple optima during sampling. Some algorithms might label these states as "mutations" of optimal states. It is important to be able to include them in final decisions, e.g., to apply additional metrics of performance specific to applications. Experience with risk-managing portfolios shows that all criteria are not best considered by lumping them all into one cost function, but rather good judgment should be applied to multiple stages of pre-processing and post-processing when performing such sampling, e.g., adding additional metrics of performance.

FUTURE TRENDS

Given financial and political motivations to merge information discussed in the Introduction, it is inevitable that many AI algorithms will be developed, and many current AI algorithms will be enhanced, to address these issues.

CONCLUSION

It seems appropriate to base an approach for propagation of generic ideas on the only system so far demonstrated to develop and nurture ideas, i.e., the neocortical brain. A statistical mechanical model of neocortical interactions, developed by the author and tested successfully in describing short-term memory and EEG indicators, Ideas by Statistical Mechanics (ISM) (Ingber, 2006) is the proposed model. ISM develops subsets of macrocolumnar activity of multivariate stochastic descriptions of defined populations, with macrocolumns defined by their local parameters within specific regions and with parameterized endogenous inter-regional and exogenous external connectivities. Tools of financial risk management, developed to process correlated multivariate systems with differing non-Gaussian distributions using modern copula analysis, importance-sampled using ASA, will enable bona fide correlations and uncertainties of success and failure to be calculated.

KEY TERMS

Copula Analysis: This transforms non-Gaussian probability distributions to a common appropriate space (usually a Gaussian space) where it makes sense to calculate correlations as second moments.

DIME: Represents diplomatic, information, military, and economic aspects of information that must be merged into coherent pattern.

Global Optimization: Refers to a collection of algorithms used to statistically sample a space of parameters or variables to optimize a system, but also often used to sample a huge space for information. There are many variants, including simulated annealing, genetic algorithms, ant colony optimization, hill-climbing, etc.

ISM: An acronym for Ideas by Statistical Mechanics in the context of the noun defined as: A belief (or system of beliefs) accepted as authoritative by some group or school. A doctrine or theory; especially, a wild or visionary theory. A distinctive doctrine, theory, system, or practice.

Meme: Alludes to a technology originally defined to explain social evolution, which has been refined to mean a gene-like analytic tool to study cultural evolution.

Memory: This may have many forms and mechanisms. Here, two major processes of neocortical memory are used for AI technologies, short-term memory (STM) and long-term memory (LTM).

Simulated Annealing (SA): A class of algorithms for sampling a huge space, which has a mathematical proof of convergence to global optimal minima. Most SA algorithms applied to most systems do not fully take advantage of this proof, but the proof often is useful to give confidence that the system will avoid getting stuck for a long time in local optimal regions.

Statistical Mechanics: A branch of mathematical physics dealing with systems with a large number of states. Applications of nonequilibrium nonlinear statistical mechanics are now common in many fields, ranging from physical and biological sciences, to finance, to computer science, etc.

INTRODUCTION

Biological systems can be viewed as information management systems, with a basic instruction set stored in each cell's DNA as "genes." For most genes, their information is enabled when they are transcribed into RNA which is subsequently translated into the proteins that form much of a cell's machinery. Although details of the process for individual genes are known, more complex interactions between elements are yet to be discovered. What we do know is that diseases can result if there are changes in the genes themselves, in the proteins they encode, or if RNAs or proteins are made at the wrong time or in the wrong quantities.

Recent advances in biotechnology led to the development of DNA microarrays, which quantitatively measure the expression of thousands of genes simultaneously and provide a snapshot of a cell's response to a particular condition. Finding patterns of gene expression that provide insight into biological endpoints offers great opportunities for revolutionizing diagnostic and prognostic medicine and providing mechanistic insight in data-driven research in the life sciences, an area with a great need for advances, given the urgency associated with diseases. However, microarray data analysis presents a number of challenges, from noisy data to the curse of dimensionality (large number of features, small number of instances) to problems with no clear solutions (*e.g.* real world mappings of genes to traits or diseases that are not yet known).

Finding patterns of gene expression in microarray data poses problems of class discovery, comparison, prediction, and network analysis which are often approached with AI methods. Many of these methods have

been successfully applied to microarray data analysis in a variety of applications ranging from clustering of yeast gene expression patterns (Eisen *et al.*, 1998) to classification of different types of leukemia (Golub *et al.*, 1999). Unsupervised learning methods (*e.g.* hierarchical clustering) explore clusters in data and have been used for class discovery of distinct forms of diffuse large B-cell lymphoma (Alizadeh *et al.*, 2000). Supervised learning methods (*e.g.* artificial neural networks) utilize a previously determined mapping between biological samples and classes (*i.e.* labels) to generate models for class prediction. A k-nearest neighbor (k-NN) approach was used to train a gene expression classifier of different forms of brain tumors and its predictions were able to distinguish biopsy samples with different prognosis suggesting that microarray profiles can predict clinical outcome and direct treatment (Nutt *et al.*, 2003). Bayesian networks constructed from microarray data hold promise for elucidating the underlying biological mechanisms of disease (Friedman *et al.*, 2000).

BACKGROUND

Cells dynamically respond to their environment by changing the set and concentrations of active genes by altering the associated RNA expression. Thus "gene expression" is one of the main determinants of a cell's state, or phenotype. For example, we can investigate the differences between a normal cell and a cancer cell by examining their relative gene expression profiles.

Microarrays quantify gene expression levels in various conditions (such as disease *vs.* normal) or across time points. For n genes and m instances (biological

Table 1. Some public online repositories of microarray data

samples), microarray measurements are stored in an n by m matrix where each row is a gene, each column is a sample and each element in the matrix is the expression level of a gene in a biological sample, where samples are instances and genes are features describing those instances. Microarray data is available through many public online repositories (Table 1). In addition, the Kent-Ridge repository (<http://sdmc.i2r.a-star.edu.sg/rp/>) contains pre-formatted data ready to use with the well-known machine learning tool Weka (Witten & Frank, 2000).

Microarray data presents some unique challenges for AI such as a severe case of the curse of dimensionality due to the scarcity of biological samples (instances). Microarray studies typically measure tens of thousands of genes in only tens of samples. This low case to variable ratio increases the risk of detecting spurious relationships. This problem is exacerbated because microarray data contains multiple sources of within-class variability, both technical and biological. The high levels of variance and low sample size make feature selection difficult. Testing thousands of genes creates a multiple testing problem, which can result in underestimating the number of false positives. Given data with these limitations, constructing models becomes under-determined and therefore prone to over-fitting.

From biology, it is also clear that genes do not act independently. Genes interact in the form of pathways or gene regulatory networks. For this reason, we need models that can be interpreted in the context of pathways. Researchers have successfully applied AI methods to microarray data preprocessing, clustering, feature selection, classification, and network analysis.

MINING MICROARRAY DATA: CURRENT TECHNIQUES, CHALLENGES AND OPPORTUNITIES FOR AI

Data Preprocessing

After obtaining microarray data, normalization is performed to account for systematic measurement biases and to facilitate between-sample comparisons (Quackenbush, 2002). Microarray data may contain missing values that may be replaced by mean replacement or k-NN imputation (Troyanskaya *et al.*, 2001).

Feature Selection

The goal of feature selection is to find genes (features) that best distinguish groups of instances (*e.g.* disease *vs.* normal) to reduce the dimensionality of the dataset. Several statistical methods including t-test, significance analysis of microarrays (SAM) (Tusher *et al.*, 2001), and analysis of variance (ANOVA) have been applied to select features from microarray data.

In classification experiments, feature selection methods generally aim to identify relevant gene subsets to construct a classifier with good performance (Inza *et al.*, 2004). Features are considered to be relevant when they can affect the class; the strongly relevant are indispensable to prediction and the weakly relevant may only sometimes contribute to prediction.

Filter methods evaluate feature subsets regardless of the specific learning algorithm used. The statistical methods for feature selection discussed above as well as rankers like information gain rankers are filters for the features to be included. These methods ignore the fact that there may be redundant features (features that are highly correlated with each other and as such one can be used to replace the other) and so do not seek to find a set of features which could perform similarly

with fewer variables while retaining the same predictive power (Guyon & Elisseeff, 2003). For this reason multivariate methods are more appropriate.

As an alternative, wrappers consider the learning algorithm as a black-box and use prediction accuracy to evaluate feature subsets (Kohavi & John, 1997). Wrappers are more direct than filter methods but depend on the particular learning algorithm used. The computational complexity associated with wrappers is prohibitive due to curse of dimensionality, so typically filters are used with forward selection (starting with an empty set and adding features one by one) instead of backward elimination (starting with all features and removing them one by one). Dimension reduction approaches are also used for multivariate feature selection.

Dimension Reduction Approaches

Principal component analysis (PCA) is widely used for dimension reduction in machine learning (Wall *et al.*, 2003). The idea behind PCA is quite intuitive: correlated objects can be combined to reduce data “dimensionality”. Relationships between gene expression profiles in a data matrix can be expressed as a linear combination such that colinear variables are regressed onto a new set of coordinates. PCA, its underlying method Single Value Decomposition (SVD), related approaches such as correspondence analysis (COA), and multidimensional scaling (MDS) have been applied to microarray data and are reviewed by Brazma & Culhane (2005). Studies have reported that COA or other dual scaling dimension reduction approaches such as spectral map analysis may be more appropriate than PCA for decomposition of microarray data (Wouters *et al.*, 2003).

While PCA considers the variance of the whole dataset, clustering approaches examine the pairwise distance between instances or features. Therefore, these methods are complementary and are often both used in exploratory data analysis. However, difficulties in interpreting the results in terms of discrete genes limit the application of these methods.

Clustering

What we see as one disease is often a collection of disease subtypes. Class discovery aims to discover these subtypes by finding groups of instances with similar expression patterns. Hierarchical clustering is an agglomerative method which starts with a singleton

and groups similar data points using some distance measure such that two data points that are most similar are grouped together in a cluster by making them children of a parent node in the tree. This process is repeated in a bottom-up fashion until all data points belong to a single cluster (corresponding to the root of the tree).

Hierarchical and other clustering approaches, including K-means, have been applied to microarray data (Causton *et al.*, 2003). Hierarchical clustering was applied to study gene expression in samples from patients with diffuse large B-cell lymphoma (DLBCL) resulting in the discovery of two subtypes of the disease. These groups were found by analyzing microarray data from biopsy samples of patients who had not been previously treated. These patients continued to be studied after chemotherapy, and researchers found that the two newly discovered disease subtypes had different survival rates, confirming the hypothesis that the subtypes had significantly different pathologies (Alizadeh *et al.*, 2000).

While clustering simply groups the given data based on pair-wise distances, when information is known *a priori* about some or all of the data *i.e.* labels, a supervised approach can be used to obtain a classifier that can predict the label of new instances.

Classification (Supervised Learning)

The large dimensionality of microarray data means that all classification methods are susceptible to over-fitting. Several supervised approaches have been applied to microarray data including Artificial Neural Networks (ANNs), Support Vector Machines (SVMs), and k-NNs among others (Hastie *et al.*, 2001).

A very challenging and clinically relevant problem is the accurate diagnosis of the primary origin of metastatic tumors. Bloom *et al.* (2004) applied ANNs to the microarray data of 21 tumor types with 88% accuracy to predict the primary site of origin of metastatic cancers with unknown origin. A classification of 84% was obtained on an independent test set with important implications for diagnosing cancer origin and directing therapy.

In a comparison of different SVM approaches, multicategory SVMs were reported to outperform other popular machine learning algorithms such as k-NNs and ANNs (Statnikov *et al.*, 2005) when applied to 11 publicly available microarray datasets related to cancer.

It is worth noting that feature selection can significantly improve classification performance.

Cross-Validation

Cross-validation (CV) is appropriate in microarray studies which are often limited by the number of instances (*e.g.* patient samples). In k -fold CV, the training set is divided into k subsets of equal size. In each iteration $k-1$ subsets are used for training and one subset is used for testing. This process is repeated k times and the mean accuracy is reported. Unfortunately, some published studies have applied CV only partially, by applying CV on the creation of the prediction rule while excluding feature selection. This introduces a bias in the estimated error rates and over-estimates the classification accuracy (Simon *et al.*, 2003). As a consequence, results from many studies are controversial due to methodological flaws (Dupuy & Simon, 2007). Therefore, models must be evaluated carefully to prevent selection bias (Ambroise & McLachlan, 2002). Nested CV is recommended, with an inner CV loop to perform the tuning of the parameters and an outer CV to compute an estimate of the error (Varma & Simon, 2006).

Several studies which have examined similar biological problems have reported poor overlap in gene expression signatures. Brenton *et al.* (2005) compared two gene lists predictive of breast cancer prognosis and found only 3 genes in common. Even though the intersection of specific gene lists is poor, the highly correlated nature of microarray data means that many gene lists may have similar prediction accuracy (Eindor *et al.*, 2004). Gene signatures identified from different breast cancer studies with few genes in common were shown to have comparable success in predicting patient survival (Buyse *et al.*, 2006).

Commonly used supervised learning algorithms yield black box models prompting the need for interpretable models that provide insights about the underlying biological mechanism that produced the data.

Network Analysis

Bayesian networks (BNs), derived from an alliance between graph theory and probability theory, can capture dependencies among many variables (Pearl, 1988, Heckerman, 1996).

Friedman *et al.* (2000) introduced a multinomial model framework for BNs to reverse-engineer networks and showed that this method differs from clustering in that it can discover gene interactions other than correlation when applied to yeast gene expression data. Spirtes *et al.* (2002) highlight some of the difficulties of applying this approach to microarray data. Nevertheless, many extensions of this research direction have been explored. Correlation is not necessarily a good predictor of interactions, and weak interactions are essential to understand disease progression. Identifying the biologically meaningful interactions from the spurious ones is challenging, and BNs are particularly well-suited for modeling stochastic biological processes.

The exponential growth of data produced by microarray technology as well as other high-throughput data (*e.g.* protein-protein interactions) call for novel AI approaches as the paradigm shifts from a reductionist to a mechanistic systems view in the life sciences.

FUTURE TRENDS

Uncovering the underlying biological mechanisms that generate these data is harder than prediction and has the potential to have far reaching implications for understanding disease etiologies. Time series analysis (Bar-Joseph, 2004) is a first step to understanding the dynamics of gene regulation, but, eventually, we need to use the technology not only to observe gene expression data but also to direct intervention experiments (Pe'er *et al.*, 2001, Yoo *et al.*, 2002) and develop methods to investigate the fundamental problem of distinguishing correlation from causation.

CONCLUSION

We have reviewed AI methods for pre-processing, clustering, feature selection, classification and mechanistic analysis of microarray data. The clusters, gene lists, molecular fingerprints and network hypotheses produced by these approaches have already shown impact; from discovering new disease subtypes and biological markers, predicting clinical outcome for directing treatment as well as unraveling gene networks. From the AI perspective, this field offers challenging problems and may have a tremendous impact on biology and medicine.

KEY TERMS

Curse of Dimensionality: A situation where the number of features (genes) is much larger than the number of instances (biological samples) which is known in statistics as $p \gg n$ problem.

Feature Selection: A problem of finding a subset (or subsets) of features so as to improve the performance of learning algorithms.

Microarray: A microarray is an experimental assay which measures the abundances of mRNA (intermediary between DNA and proteins) corresponding to gene expression levels in biological samples.

Multiple testing problem: A problem that occurs when a large number of hypotheses are tested simultaneously using a user-defined α cut off p-value which may lead to rejecting a non-negligible number of null hypotheses by chance.

Over-Fitting: A situation where a model learns spurious relationships and as a result can predict training data labels but not generalize to predict future data.

Supervised Learning: A learning algorithm that is given a training set consisting of feature vectors associated with class labels and whose goal is to learn a classifier that can predict the class labels of future instances.

Unsupervised Learning: A learning algorithm that tries to identify clusters based on similarity between features or between instances or both but without taking into account any prior knowledge.

An AI Walk from Pharmacokinetics to Marketing

INTRODUCTION

This work is intended for providing a review of real-life practical applications of Artificial Intelligence (AI) methods. We focus on the use of Machine Learning (ML) methods applied to rather real problems than synthetic problems with standard and controlled environment. In particular, we will describe the following problems in next sections:

- Optimization of Erythropoietin (EPO) dosages in anaemic patients undergoing Chronic Renal Failure (CRF).
- Optimization of a recommender system for citizen web portal users.
- Optimization of a marketing campaign.

The choice of these problems is due to their relevance and their heterogeneity. This heterogeneity shows the capabilities and versatility of ML methods to solve real-life problems in very different fields of knowledge. The following methods will be mentioned during this work:

- Artificial Neural Networks (ANNs): Multilayer Perceptron (MLP), Finite Impulse Response (FIR) Neural Network, Elman Network, Self-Organizing Maps (SOMs) and Adaptive Resonance Theory (ART).
- Other clustering algorithms: K-Means, Expectation-Maximization (EM) algorithm, Fuzzy C-Means (FCM), Hierarchical Clustering Algorithms (HCA).

- Generalized Auto-Regressive Conditional Heteroskedasticity (GARCH).
- Support Vector Regression (SVR).
- Collaborative filtering techniques.
- Reinforcement Learning (RL) methods.

BACKGROUND

The aim of this communication is to emphasize the capabilities of ML methods to deliver practical and effective solutions in difficult real-world applications. In order to make the work easy to read we focus on each of the three separate domains, namely, Pharmacokinetics (PK), Web Recommender Systems and Marketing.

Pharmacokinetics

Clinical decision-making support systems have used Artificial Intelligence (AI) methods since the end of the fifties. Nevertheless, it was only during the nineties that decision support systems were routinely used in clinical practice on a significant scale. In particular, ANNs have been widely used in medical applications the last two decades (Lisboa, 2002). One of the first relevant studies involving ANNs and Therapeutic Drug Monitoring was (Gray, Ash, Jacobi, & Michel, 1991). In this work, an ANN-based drug interaction warning system was developed with a computerized real-time entry medical records system. A reference work in this field is found in (Brier, Zurada, & Aronoff, 1995), in which the capabilities of ANNs and NONMEN are benchmarked.

Focusing on problems that are closer to the real-life application that will be described in next section, there are also a number of recent works involving the use of ML for drug delivery in kidney disease. For instance, a comparison of renal-related adverse drug reactions between rofecoxib and celecoxib, based on the WHO/Uppsala Monitoring Centre safety database, was carried out by (Zhao, Reynolds, Lejkowith, Whelton, & Arellano, 2001). Disproportionality in the association between a particular drug and renal-related adverse drug reactions was evaluated using a Bayesian confidence propagation neural network method. A study of prediction of cyclosporine dosage in patients after kidney transplantation using neural networks and kernel-based methods was carried out in (Camps et al., 2003). In (Gaweda, Jacobs, Brier, & Zurada, 2003), a pharmacodynamic population analysis in CRF patients using ANNs was performed. Such models allow for adjusting the dosing regime. Finally, in (Martín et al., 2003), the use of neural networks was proposed for the optimization of EPO dosage in patients undergoing anaemia connected with CRF.

Web Recommender Systems

Recommender systems are widely used in web sites including Google. The main goal of these systems is to recommend objects which a user might be interested in. Two main approaches have been used: content-based and collaborative filtering (Zukerman & Albrecht, 2001), although other kinds of techniques have also been proposed (Burke, 2002).

Collaborative recommenders aggregate ratings of recommendations of objects, find user similarities based on their ratings, and finally provide new recommendations based on inter-user comparisons. Some of the most relevant systems using this technique are GroupLens/NetPerceptions and Recommender. The main advantage of collaborative techniques is that they are independent from any machine-readable representation of the objects, and that they work well for complex objects where subjective judgements are responsible for much of the variation in preferences.

Content-based learning is used when a user's past behaviour is a reliable indicator of his/her future behaviour. It is particularly suitable for situations in which users tend to exhibit idiosyncratic behaviour. However, this approach requires a system to collect relatively large amounts of data from each user in order

to enable the formulation of a statistical model. Examples of systems of this kind are text recommendation systems like the newsgroup filtering system, NewsWeeder, which uses words from its texts as features.

Marketing

The latest marketing trends are more concerned about maintaining current customers and optimizing their behaviour than getting new ones. For this reason, relational marketing focuses on what a company must do to achieve this objective. The relationships between a company and its costumers follow a sequence of action-response system, where the customers can modify their behaviour in accordance with the marketing actions developed by the company.

The development of a good and individualized policy is not easy because there are many variables to take into account. Applications of this kind can be viewed as a Markov chain problem, in which a company decides what action to take once the customer properties in the current state (time t), are known. Reinforcement Learning (RL) can be used to solve this task since previous applications have demonstrated its suitability in this area. In (Sun, 2003), RL was applied to analyse mailing by studying how an action in time t influences actions in following times. In (Abe et al., 2002) and (Pednault, Abe & Zadrozny., 2002), several RL algorithms were benchmarked in mailing problems. In (Abe, 2004), RL was used to optimize cross channel marketing.

AI CONTRIBUTIONS IN REAL-LIFE APPLICATIONS

Previous section showed a review of related work. In this section, we will focus on showing authors' experience in using AI to solve real-life problems. In order to show up the versatility of AI methods, we will focus on particular applications from three different fields of knowledge, the same that were reviewed in previous section.

Pharmacokinetics

Although we have also worked with other pharmacokinetic problems, in this work, we focus on maybe the most relevant problem, which is the

optimization of EPO dosages in patients within a haemodialysis program. Patients who suffer from CRF tend to suffer from an associated anaemia, as well. EPO is the treatment of choice for this kind of anaemia. The use of this drug has greatly reduced cardiovascular problems and the necessity of multiple transfusions. However, EPO is expensive, making the already costly CRF program even more so. Moreover, there are significant risks associated with EPO such as thrombo-embolisms and vascular problems, if Haemoglobin (Hb) levels are too high or they increase too fast. Consequently, optimizing dosage is critical to ensure adequate pharmacotherapy as well as a reasonable treatment cost.

Population models, widely used by Pharmacokinetics' researchers, are not suitable for this problem since the response to the treatment with EPO is highly dependent on the patient. The same dosages may have very different responses in different patients, most notably the so-called EPO-resistant patients, who do not respond to EPO treatment, even after receiving high dosages. Therefore, it is preferable to focus on an individualized treatment.

Our first approach to this problem was based on predicting the Hb level given a certain administered dose of EPO. Although the final goal is to individualize EPO doses, we did not predict EPO dose but Hb level. The reason is that EPO predictors would model physician's protocol whereas Hb predictors model body's response to the treatment, hence being a more "objective" approach. In particular, the following models were used: GARCH (Hamilton, 1994), MLP, FIR neural network, Elman's recurrent neural network and SVR (Haykin, 1999). Accurate prediction models were obtained, especially when using ANNs and SVR. Dynamic neural networks (i.e., FIR and recurrent) did not outperform notably the static MLP probably due to the short length of the time series (Martín et al., 2003). An easy-to-use software application was developed to be used by clinicians, in which after filling in patients' data and a certain EPO dose, the predicted Hb level for next month was shown.

Although prediction models were accurate, we realized that this prediction approach had a major flaw. Despite obtaining accurate models, we had not yet achieved a straightforward way to transfer the extracted knowledge to daily clinical practice, because clinicians had to "play" with different doses to analyse the best solution to attain a certain Hb level. It would

be better to have an automatic model that suggests the actions to be made in order to attain the targeted range of Hb, rather than this "indirect" approach. This reflection made us research on new models, and we came up with the use of RL (Sutton & Barto, 1998). We are currently working on this topic but we have already achieved promising results, finding policies (sequence of actions) that appear to be better than those followed in the hospital, i.e., there are a higher number of patients within the desired target of Hb at the end of the treatment (Martín et al., 2006a).

Web Recommender Systems

A completely different application is described in this subsection, namely, the development of web recommender systems. The authors proposed a new approach to develop recommender systems based on collaborative filtering, but also including an analysis of the feasibility of the recommender by using a prediction stage (Martín et al., 2006b).

The very basic idea was to use clustering algorithms in order to find groups of similar users. The following clustering algorithms were taken into account: K-Means, FCM, HCA, EM algorithm, SOMs and ART. New users were assigned to one of the groups found by these clustering algorithms, and then they were recommended with web services that were usually accessed by other users of his/her same group, but had not yet been accessed by these new users (in order to maximize the usefulness of the approach). Using controlled data sets, the study concluded that ART and SOMs showed a very good behaviour with data sets of very different characteristics, whereas HCA and EM showed an acceptable behaviour provided that the dimensionality of the data set was not too high and the overlap was slight. Algorithms based on K-Means achieved the most limited success in the acceptance of offered recommendations.

Even though the use of RL was only slightly studied, it seems to be a suitable choice for this problem, since the internal dynamics of the problem is easily tackled by RL, and moreover the interference between the recommendation interface and the user can be minimized with an adequate definition of the rewards (Hernández, Gaudioso, & Boticario, 2004).

Marketing

The last application that will be mentioned in this communication is related to marketing. One way to increase the loyalty of customers is by offering them the opportunity to obtain some gifts as the result of their purchases from a certain company. The company can give *virtual credits* to anyone who buys certain articles, typically those that the company is interested in promoting. After a certain number of purchases, the customers can exchange their virtual credits for the gifts offered by the company. The problem is to establish the appropriate number of virtual credits for each promoted item. In accordance with the company policy, it is expected that the higher the credit assignment, the higher the amount of purchases. However, the company's profits are lower since the marketing campaign adds an extra cost to the company. The goal is to achieve a trade-off by establishing an optimal policy.

We proposed a RL approach to optimize this marketing campaign. This particular application, whose characteristics are described below, is much more difficult than the other RL approaches to marketing mentioned in the Background Section. This is basically because there are many more different actions that can be taken. The information used for the study corresponds to five months of the campaign, involving 1,264,862 transactions, 1,004 articles and 3,573 customers.

RL can deal with intrinsic dynamics, and besides, it has the attractive advantage that is able to maximize the so-called long-term reward. This is especially relevant in this application since the company is interested in maximizing the profits at the end of the campaign, and a customer who do not produce much profits in the first months of the campaign, may however make many profitable transactions in the future.

Our first results showed that profits using a policy based on RL instead of the policy followed by the company so far, could even double long-term profits at the end of the campaign (Gómez et al., 2005).

CONCLUSION AND FUTURE TRENDS

This paper has shown the capabilities and versatility of different AI methods to be applied to real-life problems, illustrated with three specific applications in different domains. Clearly, the methodology is generic and applies equally well to many other fields,

provided that the information contained in the data is sufficiently rich to require non-linear modelling and is capable of supporting a predictive performance that is of practical value.

As a next future trend, it should be emphasized that AI methods are increasingly popular for business applications in recent years, challenging classical business models.

In the particular case of RL, the commercial potential of this powerful methodology has been significantly underestimated, as it is applied almost exclusively to Robotics. We feel that it is a methodology still to be exploited in many real applications, as we have shown in this paper.

KEY TERMS

Agent: In RL terms, it is the responsible of making decisions according to observations of its environment.

Environment: In RL terms, it is every external condition to the agent.

Exploration-Exploitation Dilemma: It is a classical RL dilemma, in which a trade-off solution must be achieved. Exploration means random search of new actions in order to achieve a likely (but yet unknown) better reward than all the known ones, while exploitation is focused on exploiting the current knowledge for the maximization of the reward (*greedy* approach).

Life-Time Value: It is a measure widely used in marketing applications that offers the long-term result that has to be maximized.

Reward: In RL terms, the immediate reward is the value returned by the environment to the agent depending on the taken action. The long-term reward is the sum of all the immediate rewards throughout a complete decision process.

Sensitivity: Similar measure that offers the ratio of positives that are correctly classified by the model. (Refer to Specificity.)

Specificity: Success rate measure in a classification problem. If there are two classes (namely, positive and negative), specificity measures the ratio of negatives that are correctly classified by the model.

Algorithms for Association Rule Mining

University of Delhi, India

INTRODUCTION

Association Rule Mining (ARM) is one of the important data mining tasks that has been extensively researched by data-mining community and has found wide applications in industry. An Association Rule is a pattern that implies co-occurrence of events or items in a database. Knowledge of such relationships in a database can be employed in strategic decision making in both commercial and scientific domains.

A typical application of ARM is market basket analysis where associations between the different items are discovered to analyze the customer's buying habits. The discovery of such associations can help to develop better marketing strategies. ARM has been extensively used in other applications like spatial-temporal, health care, bioinformatics, web data etc (Hipp J., Güntzer U., Nakhaeizadeh G. 2000).

An association rule is an implication of the form $X \rightarrow Y$ where X and Y are independent sets of attributes/items. An association rule indicates that if a set of items X occurs in a transaction record then the set of items Y also occurs in the same record. X is called the antecedent of the rule and Y is called the consequent of the rule. Processing massive datasets for discovering co-occurring items and generating interesting rules in reasonable time is the objective of all ARM algorithms. The task of discovering co-occurring sets of items cannot be easily accomplished using SQL, as a little reflection will reveal. Use of 'Count' aggregate query requires the condition to be specified in the where clause, which finds the frequency of only one set of items at a time. In order to find out all sets of co-occurring items in a database with n items, the number of queries that need to be written is exponential in n . This is the prime motivation for designing algorithms

for efficient discovery of co-occurring sets of items, which are required to find the association rules.

In this article we focus on the algorithms for association rule mining (ARM) and the scalability issues in ARM. We assume familiarity of the reader with the motivation and applications of association rule mining

BACKGROUND

Let $I = \{i_1, i_2, \dots, i_n\}$ denote a set of items and D denote a database of N transactions. A typical transaction $T \in D$ may contain a subset X of the entire set of items I and is associated with a unique identifier TID . An *item-set* is a set of one or more items i.e. X is an item-set if $X \subseteq I$. A *k-item-set* is an item-set of cardinality k . A transaction is said to contain an item-set X if $X \subseteq T$. *Support* of an item set X , also called *Coverage* is the fraction of transactions that contain X . It denotes the probability that a transaction contains X .

$$Support(X) = P(X) = \frac{\text{No. of transactions containing } X}{N}$$

An item-set having support greater than the user specified support threshold (ms) is known as *frequent item-set*.

An *association rule* is an implication of the form $X \rightarrow Y$ [*Support, Confidence*] where $X \subset I$, $Y \subset I$ and $X \cap Y = \emptyset$, where *Support* and *Confidence* are rule evaluation metrics. *Support* of a rule $X \rightarrow Y$ in D is ' S ' if $S\%$ of transactions in D contain $X \cup Y$. It is computed as:

$$Support(X \rightarrow Y) = P(X \cup Y) = \frac{\text{No. of transaction containing } X \cup Y}{N}$$

Support indicates the prevalence of a rule. In a typical market basket analysis application, rules with very low support values represent rare events and are likely to be uninteresting or unprofitable. *Confidence* of a rule measures its strength and provides an indication of the reliability of prediction made by the rule. A rule $X \rightarrow Y$ has a confidence 'C' in D if C % of transactions in D that contain X , also contain Y . Confidence is computed, as the conditional probability of Y occurring in a transaction, given X is present in the same transaction, i.e.

$$\text{Confidence}(X \rightarrow Y) = P(Y/X) = \frac{P(X \cup Y)}{P(X)} = \frac{\text{Support}(X \cup Y)}{\text{Support}(X)}$$

A rule generated from frequent item-sets is *strong* if its confidence is greater than the user specified confidence threshold (mc). Fig. 1 shows an example database of five transactions and shows the computation of support and confidence of a rule.

The objective of Association Rule Mining algorithms is to discover the set of strong rules from a given database as per the user specified ms and mc thresholds. Algorithms for ARM essentially perform two distinct tasks: (1) Discover frequent item-sets. (2) Generate strong rules from frequent item-sets.

The first task requires counting of item-sets in the database and filtering against the user specified threshold (ms). The second task of generating rules from frequent item-sets is a straightforward process of generating subsets and checking for the strength. We describe below the general approaches for finding frequent item-sets in association rule mining algorithms. The second task is trivial as explained in the last section of the article.

APPROACHES FOR GENERATING FREQUENT ITEM-SETS

If we apply a brute force approach to discover frequent item-sets, the algorithm needs to maintain counters for all $2^n - 1$ item-sets. For large values of n that are common in the datasets being targeted for mining, maintaining such large number of counters is a daunting task. Even if we assume availability of such large memory, indexing of these counters also presents a challenge. Data mining researchers have developed numerous algorithms for efficient discovery of frequent item-sets.

The earlier algorithms for ARM discovered all frequent item-sets. Later it was shown by three independent groups of researchers (Pasquier N., Bastide Y., Taouil R. & Lakhal L. 1999), (Zaki M.J. 2000), (Stumme G., 1999), that it is sufficient to discover frequent closed item-sets (FCI) instead of all frequent item-sets (FI). FCI are the item-sets whose support is not equal to the support of any of its proper superset. FCI is a reduced, complete and loss less representation of frequent item-sets. Since FCI are much less in number than FI, computational expense for ARM is drastically reduced.

Figure 2 summarizes different approaches used for ARM. We briefly describe these approaches.

Discovery of Frequent Item-Sets

Level-Wise Approach

Level wise algorithms start with finding the item-sets of cardinality one and gradually work up to the frequent item-sets of higher cardinality. These algorithms use anti-monotonic property of frequent item-sets accord-

Figure 1. Computation of support and confidence of a rule in an example database

| TID | Items |
|-----|-------|
| 1 | BCD |
| 2 | BCDE |
| 3 | AC |
| 4 | BDE |
| 5 | AB |

Let $ms=40\%$, $mc=70\%$
 Consider the association rule $B \rightarrow D$,
 $\text{support}(B \rightarrow D) = 3/5 = 60\%$
 $\text{confidence}(B \rightarrow D) = \text{support}(B \cap D) / \text{support}(B)$
 $= 3/4 = 75\%$
 The rule $B \rightarrow D$ is a strong rule.

Figure 2. Approaches for ARM algorithms

ing to which, no superset of an infrequent item-set can be frequent.

Agarwal et al. (Agarwal, R., Imielinski T., & Swami A. 1993), (Agarwal, R., & Swami A., 1994) proposed Apriori algorithm, which is the most popular iterative algorithm in this category. It starts, with finding the frequent item-sets of size one and goes up level by level, finding candidate item-sets of size k by joining item-sets of size $k-1$. Two item-sets, each of size $k-1$ join to form an item-set of size k if and only if they have first $k-2$ items common. At each level the algorithm prunes the candidate item-sets using anti-monotonic property and subsequently scans the database to find the support of pruned candidate item-sets. The process continues till the set of frequent item-sets is non-empty. Since each iteration requires a database scan, maximum number of database scans required is same as the size of maximal item-set. Fig. 3 and Fig 4 gives the pseudo code of Apriori algorithm and a running example respectively.

Two of the major bottlenecks in Apriori algorithm are i) number of passes and ii) number of candidates generated. The first is likely to cause I/O bottleneck and the second causes heavy load on memory and CPU usage. Researchers have proposed solutions to these problems with considerable success. Although detailed discussion of these solutions is beyond the scope of this article, a brief mention is necessary.

Hash techniques reduce the number of candidates by making a hash table and discarding a bucket if it has support less than the ms . Thus at each level memory requirement is reduced because of smaller candidate set. The reduction is most significant at lower levels. Maintaining a list of transaction ids for each candidate set reduces the database access. Dynamic Item-set Counting algorithm reduces the number of scans by

counting candidate sets of different cardinality in a single scan (Brin S., Motwani R., Ullman J.D., & Tsur S. 1997). Pincer Search algorithm uses a bi-directional strategy to prune the candidate set from top (maximal) and bottom (1-itemset) (Lin D. & Kedem Z.M. 1998). Partitioning and Sampling strategies have also been proposed to speed up the counting task. An excellent comparison of Apriori algorithm and its variants has been given in (Hipp J., Güntzer U., Nakhaeizadeh G. 2000).

Tree Based Algorithms

Tree based algorithms have been proposed to overcome the problem of multiple database scans. These algorithms compress (sometimes lossy) the database into a tree data structure and reduce the number of database scans appreciably. Subsequently the tree is used to mine for support of all frequent item-sets.

Set-Enumeration tree used in Max Miner algorithm (Bayardo R.J. 1998) orders the candidate sets while searching for maximal frequent item-sets. The data structure facilitates quick identification of long frequent item-sets based on the information gathered during each pass. The algorithm is particularly suitable for dense databases with maximal item-sets of high cardinality.

Han et. al. (Han, J., Pei, J., & Yin, Y. 2000) proposed Frequent Pattern (FP)-growth algorithm which performs a database scan and finds frequent item-sets of cardinality one. It arranges all frequent item-sets in a table (header) in the descending order of their supports. During the second database scan, the algorithm constructs in-memory data structure called FP-Tree by inserting each transaction after rearranging it in descending order of the support. A node in FP-Tree stores a single attribute so that each path in the tree

Figure 3. Apriori algorithm

```

Input: Database D of N transactions
      ms, mc
Output: Set L of frequent item-sets

Procedure

1. scan the database and find  $L_1 = \{\text{frequent 1-item sets}\}$ 
2.  $k = 2$ 
3. while  $L_{k-1} \neq \emptyset$ 
4.    $C_k = \text{gen\_candidate}(L_{k-1})$ 
5.    $L_k = \text{prune}(C_k, L_{k-1})$ 
6.    $k++$ 
7. return  $L = \cup_k L_k$ 

gen_candidate( $L_{k-1}$ )
1. for each  $l_1 \in L_{k-1}$ 
2.   for each  $l_2 \in L_{k-1}$ 
3.     if  $(l_1[1] = l_2[1]) \wedge (l_1[2] = l_2[2]) \wedge \dots \wedge (l_1[k-2] = l_2[k-2]) \wedge$ 
        $(l_1[k-1] < l_2[k-1])$  then
4.        $C_k = l_1[1] l_1[2] \dots l_1[k-2] l_1[k-1] l_2[k-1]$ 

Prune( $C_k, L_{k-1}$ )
// remove candidate itemsets having infrequent subsets
1. for  $c \in C_k$ 
2.   for each  $(k-1)$  subset  $s$  of  $c$ 
3.     if  $s \notin L_{k-1}$  then
4.       remove  $c$  from  $C_k$ 
5. for each  $c \in C_k$ 
6.   scan the database to find support of  $c$ 
7.   add  $c$  to  $L_k$  if  $\text{support}(c) \geq ms$ 
8. return  $L_k$ 

```

represents and counts the corresponding record in the database. A link from the header connects all the nodes of an item. This structural information is used while mining the FP-Tree. FP-Growth algorithm recursively generates sub-trees from FP-Trees corresponding to each frequent item-set.

Coenen et. al. (Coenen F., Leng P., & Ahmed S. 2004) proposed Total Support Tree (T-Tree) and Partial Support Tree (P-Tree) data structures which offer significant advantage in terms of storage and execution. These data structures are compressed set enumeration trees and are constructed after one scan of the database and stores all the item-sets as distinct records in database.

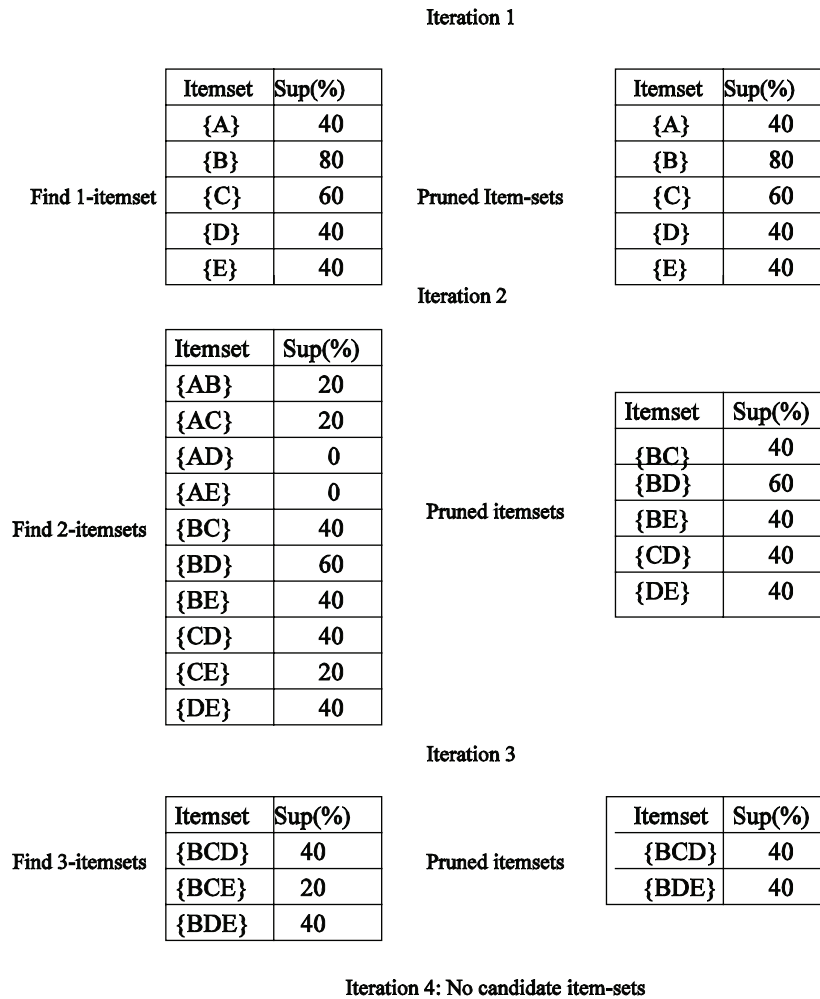

Discovery of Frequent Closed Item-Sets

Level Wise Approach

Pasquier et. al. (Pasquier N., Bastide Y., Taouil R. & Lakhal L. 1999) proposed Close method to find

Frequent Closed Item-sets (FCI). This method finds closures based on Galois closure operators and computes the generators. Galois closure operator $h(X)$ for some $X \subseteq I$ is defined as the intersection of transactions in D containing item-set X . An item-set X is a closed item-set if and only if $h(X) = X$. One of the smallest arbitrarily chosen item-set p , such that $h(p) = X$ is known as generator of X .

Close method is based on Apriori algorithm. It starts from 1- item-sets, finds the closure based on Galois closure operator, goes up level by level computing generators and their closures (i.e. FCI) at each level. At each level, candidate generator item-sets of size k are found by joining generator item-sets of size $k-1$ using the combinatorial procedure used in Apriori algorithm. The candidate generators are pruned using two strategies i) remove candidate generators whose all subsets are not frequent ii) remove the candidate generators if closure of one of its subsets is superset of the generator. Subsequently algorithm finds the support of pruned candidate generator. Each iteration requires

Figure 4. Running example of apriori algorithm for finding frequent itemsets ($ms = 40\%$)

one pass over the database to construct the set of FCI and count their support.

Tree Based Approach

Wang et. al. (Wang J., Han J. & Pei J. 2003) proposed Closet+ algorithm to compute FCI and their supports using FP-tree structure. The algorithm is based on divide and conquers strategy and computes the local frequent items of a certain prefix by building and scanning its projected database.

Concept Lattice Based Approach

Concept lattice is a core structure of *Formal Concept Analysis (FCA)*. *FCA* is a branch of mathematics based on *Concept* and *Concept hierarchies*. *Concept (A,B)* is defined as a pair of set of objects *A* (known as *extent*) and set of attributes *B* (known as *intent*) such that set of all attributes belonging to *extent A* is same as *B* and set of all objects containing attributes of *intent B* is same as *A*. In other words, no object other than objects of set *A* contains all attributes of *B* and no attribute other than attributes in set *B* is contained in all objects of set *A*. *Concept lattice* is a complete lattice of all *Concepts*. Stumme G., (1999) discovered that *intent*

Exhibit A.

```

add extent {all transactions} in the list of extents
For each item  $i \in I$ 
    for each set  $X$  in the list of extents
        find  $X \cap \{\text{set of transactions containing } i\}$ 
        include in the list of extents if not included earlier
    EndFor
EndFor

```

B of the *Concept* (A, B) represents the closed item-set, which implies that all algorithms for finding Concepts can be used to find closed item-sets. Kuznetsov S.O., & Obiedkov S.A. (2002) provides a comparison of performance of various algorithms for concepts. The naïve method to compute Concepts, proposed by Ganter is given in Exhibit A.

This method generates all the *Concepts* i.e. all closed item-sets. Closed item-sets generated using this method in example 1 are $\{A\}, \{B\}, \{C\}, \{A, B\}, \{A, C\}, \{B, D\}, \{B, C, D\}, \{B, D, E\}, \{B, C, D, E\}$. Frequent Closed item-sets are $\{A\}, \{B\}, \{C\}, \{B, D\}, \{B, C, D\}, \{B, D, E\}$.

Concept lattice for frequent closed item-sets is given in Figure 5.

Figure 5. Concept lattice

Generating Association Rules

Once all frequent item-sets are known, association rules can be generated in a straightforward manner by finding all subsets of an item-sets and testing the strength (Han J., & Kamber M., 2006). The pseudo code for this algorithm is given in Exhibit B.

Based on the above algorithm, *strong* rules generated from frequent item-set BCD in Example 1 are:

$BC \rightarrow D$, conf=100%
 $CD \rightarrow B$, conf=100%
 where $mc = 70\%$

There are two ways to find association rules from frequent closed item-sets:

- compute frequent item-sets from FCI and then find the association rules
- generate rules directly using FCI.

Close method uses the first approach, which generates lot of redundant rules while method proposed by Zaki (Zaki M.J., 2000), (Zaki, M.J., & Hsiao C., J., 2005) uses the second approach and derives rules

directly from the *Concept lattice*. The association rules thus derived are *non-redundant rules*. For example, set of *strong* rules generated using Close method in Example 1 is $\{BC \rightarrow D, CD \rightarrow B, D \rightarrow B, E \rightarrow B, E \rightarrow D, E \rightarrow BD, BE \rightarrow D, DE \rightarrow B\}$. For the same example, set of non-redundant strong rules generated using *Concept Lattice* approach is $\{D \rightarrow B, E \rightarrow BD, BC \rightarrow D, CD \rightarrow B\}$. We can observe here that all rules can be derived from the reduced non-redundant set of rules.

Scalability issues in Association Rule Mining

Scalability issues in ARM have motivated development of incremental and parallel algorithms. Incremental algorithms for ARM preserve the counts of selective item-sets and reuse this knowledge later to discover frequent item-sets from augmented database. Fast update algorithm (FUP) is the earliest algorithm based on this idea. Later different algorithms are presented based on sampling (Hipp J., Guntzer U., & Nakhaeizadeh G., 2000).

Parallel algorithms partition either the dataset for counting or the set of counters, across different ma-

Exhibit B.

```

For each frequent item-set  $I$ ,
    generate all non-empty subsets of  $I$ 
    For every non-empty subset  $s$  of  $I$ ,
        Output the rule  $s \rightarrow (I-s)$  if  $\text{support}(I) / \text{support}(s) \geq mc$ 
    EndFor
EndFor

```

chines to achieve scalability (Hipp J., Guntzer U., & Nakhaeizadeh G., 2000). Algorithms, which partition the dataset exchange counters while the algorithms, which partition the counters, exchange datasets incurring high communication cost.

FUTURE TRENDS

Discovery of Frequent Closed Item-sets (FCI) is a big lead in ARM algorithms. With the current growth rate of databases and increasing applications of ARM in various scientific and commercial applications we envisage tremendous scope for research in parallel, incremental and distributed algorithms for FCI. Use of lattice structure for FCI offers promise of scalability. On line mining on streaming datasets using FCI approach is an interesting direction to work on.

CONCLUSION

The article presents the basic approach for Association Rule Mining, focusing on some common algorithms for finding frequent item-sets and frequent closed item-sets. Various approaches have been discussed to find such item-sets. Formal Concept Analysis approach for finding frequent closed item-sets is also discussed. Generation of rules from frequent items-sets and frequent closed item-sets is briefly discussed. The article addresses the scalability issues involved in various algorithms.

KEY TERMS

Association Rule: An Association rule is an implication of the form $X \rightarrow Y$ where $X \subset I$, $Y \subset I$ and $X \cap Y = \emptyset$, I denotes the set of items.

Data Mining: Extraction of interesting, non-trivial, implicit, previously unknown and potentially useful information or patterns from data in large databases.

Formal Concept: A formal context $K = (G, M, I)$ consists of two sets G (objects) and M (attributes) and a relation I between G and M . For a set $A \subseteq G$ of objects

$A' = \{m \in M \mid gIm \text{ for all } g \in A\}$ (the set of all attributes common to the objects in A). Correspondingly, for a set B of attributes we define

$B' = \{g \in G \mid gIm \text{ for all } m \in B\}$ (the set of objects common to the attributes in B).

A formal concept of the context (G, M, I) is a pair (A, B) with $A \subseteq G, B \subseteq M$,

$A' = B$ and $B' = A$

A is called the extent and B is the intent of the concept (A, B) .

Frequent Closed Item-Set: An item-set X is a closed item-set if there exists no item-set X' such that:

- X' is a proper superset of X ,
- Every transaction containing X also contains X' .

A closed item-set X is frequent if its support exceeds the given support threshold.

Galois Connection: Let $D = (O, I, R)$ be a data mining context where O and I are finite sets of objects (transactions) and items respectively. $R \subseteq O \times I$ is a binary relation between objects and items. For $O \subseteq O$, and $I \subseteq I$, we define as shown in Exhibit C.

$f(O)$ associates with O the items common to all objects $o \in O$ and $g(I)$ associates with I the objects related to all items $i \in I$. The couple of applications (f, g) is a Galois connection between the power set of O (i.e. 2^O) and the power set of I (i.e. 2^I).

The operators $h = f \circ g$ in 2^I and $h' = g \circ f$ in 2^O are Galois closure operators. An item-set $C \subseteq I$ from D is a closed item-set iff $h(C) = C$.

Generator Item-Set: A generator p of a closed item-set c is one of the smallest item-sets such that $h(p) = c$.

Non-Redundant Association Rules: Let R_i denote the rule $X_1^i \rightarrow X_2^i$, where $X_1, X_2 \subseteq I$. Rule R_1 is more general than rule R_2 provided R_2 can be generated by adding additional items to either the antecedent or consequent of R_1 . Rules having the same support and confidence as

Exhibit C.

$$f(O): 2^O \rightarrow 2^I$$

$$f(O) = \{i \in I \mid \forall o \in O, (o, i) \in R\}$$

$$g(I): 2^I \rightarrow 2^O$$

$$g(I) = \{o \in O \mid \forall i \in I, (o, i) \in R\}$$

more general rules are the redundant association rules.
Remaining rules are non-redundant rules.

Ambient Intelligence

Fariba Sadri

Imperial College London, UK

Kostas Stathis

Royal Holloway, University of London, UK

INTRODUCTION

In recent years much research and development effort has been directed towards the broad field of **ambient intelligence (AmI)**, and this trend is set to continue for the foreseeable future. AmI aims at seamlessly integrating services within smart infrastructures to be used at home, at work, in the car, on the move, and generally in most environments inhabited by people. It is a relatively new paradigm rooted in ubiquitous computing, which calls for the integration and convergence of multiple disciplines, such as sensor networks, portable devices, intelligent systems, human-computer and social interactions, as well as many techniques within artificial intelligence, such as planning, contextual reasoning, speech recognition, language translation, learning, adaptability, and temporal and hypothetical reasoning.

The term AmI was coined by the European Commission, when in 2001 one of its Programme Advisory Groups launched the AmI challenge (Ducatel et al., 2001), later updated in 2003 (Ducatel et al., 2003). But although the term AmI originated from Europe, the goals of the work have been adopted worldwide, see for example (The Aware Home, 2007), (The Oxygen Project, 2007), and (The Sony Interaction Lab, 2007).

The foundations of AmI infrastructures are based on the impressive progress we are witnessing in wireless technologies, sensor networks, display capabilities, processing speeds and mobile services. These developments help provide much useful (raw) information for AmI applications. Further progress is needed in taking full advantage of such information in order to provide the degree of intelligence, flexibility and naturalness envisaged. This is where **artificial intelligence** and **multi-agent techniques** have important roles to play.

In this paper we will review the progress that has been made in intelligent systems, discuss the role of

artificial intelligence and **agent technologies** and focus on the application of AmI for independent living.

BACKGROUND

Ambient intelligence is a vision of the information society where normal working and living environments are surrounded by **embedded intelligent devices** that can merge unobtrusively into the background and work through intuitive interfaces. Such devices, each specialised in one or more capabilities, are intended to work together within an infrastructure of **intelligent systems**, to provide a multitude of services aimed at generally improving safety and security and improving quality of life in ordinary living, travelling and working environments.

The European Commission identified four AmI scenarios (Ducatel et al. 2001, 2003) in order to stimulate imagination and initiate and structure research in this area. We summarise two of these to provide the flavour of AmI visions.

AmI Scenarios:

1. Dimitrios is taking a coffee break and prefers not to be disturbed. He is wearing on his clothes or body a voice activated digital avatar of himself, known as Digital Me (D-Me). D-Me is both a learning device, learning about Dimitrios and his environment, and an acting device offering communication, processing and decision-making functionalities. During the coffee break D-Me answers the incoming calls and emails of Dimitrios. It does so smoothly in the necessary languages, with a re-production of Dimitrios' voice and accent. Then D-Me receives a call from Dimitrios' wife, recognises its urgency and passes it on to Dimitrios. At the same time it catches a message from an older person's D-Me,

located nearby. This person has left home without his medication and would like to find out where to access similar drugs. He has asked his D-Me, in natural language, to investigate this. Dimitrios happens to suffer from a similar health problem and uses the same drugs. His D-Me processes the incoming request for information, and decides neither to reveal Dimitrios' identity nor offer direct help, but to provide the elderly person's D-Me with a list of the closest medicine shops and potential contact with a self-help group.

2. Carmen plans her journey to work. It asks AmI, by voice command, to find her someone with whom she can share a lift to work in half an hour. She then plans the dinner party she is to give that evening. She wishes to bake a cake, and her e-fridge flashes a recipe on the e-fridge screen and highlights the ingredients that are missing. Carmen completes her shopping list on the screen and asks for it to be delivered to the nearest distribution point in her neighbourhood. All goods are smart tagged, so she can check the progress of her virtual shopping from any enabled device anywhere, and make alterations. Carmen makes her journey to work, in a car with dynamic traffic guidance facilities and traffic systems that dynamically adjust speed limits depending on congestion and pollution levels. When she returns home the AmI welcomes her and suggests that on the next day she should telework, as a big demonstration is planned in downtown.

The demands that drive AmI and provide opportunities are for improvement of safety and quality of life, enhancements of productivity and quality of products and services, including public services such as hospitals, schools, military and police, and industrial innovation. AmI is intended to facilitate human contact and community and cultural enhancement, and ultimately it should inspire trust and confidence.

Some of the technologies required for AmI are summarised in Figure 1.

AmI work builds on ubiquitous computing and sensor network and mobile technologies. To provide the intelligence and naturalness required, it is our view that significant contributions can come from advances in artificial intelligence and agent technologies. **Artificial intelligence** has a long history of research on planning, scheduling, temporal reasoning, fault diagnosis, hypothetical reasoning, and reasoning with incomplete and uncertain information. All of these are techniques that can contribute to AmI where actions and decisions have to be taken in real time, often with dynamic and uncertain knowledge about the environment and the user. Agent technology research has concentrated on agent architectures that combine several, often cognitive, capabilities, including reactivity and adaptability, as well as the formation of agent societies through communication, norms and protocols.

Recent work has attempted to exploit these techniques for AmI. In (Augusto and Nugent 2004) the use of temporal reasoning combined with active data-

Figure 1. Components of Ambient Intelligence

bases are explored in the context of smart homes. In (Sadri 2007) the use of temporal reasoning together with agents is explored to deal with similar scenarios, where information observed in a home environment is evaluated, deviations from normal behaviour and risky situations are recognised and compensating actions are recommended.

The relationship of AmI to **cognitive agents** is motivated by (Stathis and Toni 2004) who argue that computational logic elevates the level of the system to that of a user. They advocate the **KGP agent model** (Kakas, et al 2004) to investigate how to assist a traveller to act independently and safely in an unknown environment using a personal communicator. (Augusto et al 2006) address the process of taking decisions in the presence of conflicting options. (Li and Ji 2005) offer a new probabilistic framework based on Bayesian Networks for dealing with ambiguous and uncertain sensory observations and users' changing states, in order to provide correct assistance.

(Amigoni et al 2005) address the goal-oriented aspect of AmI applications, and in particular the planning problem within AmI. They conclude that a combination of centralised and distributed planning capabilities are required, due to the distributed nature of AmI and the participation of heterogeneous agents, with different capabilities. They offer an approach based on the Hierarchical Task Networks taking the perspective of a multi-agent paradigm for AmI.

The paradigm of **embedded agents** for AmI environments with a focus on developing learning and adaptation techniques for the agents is discussed in (Hagras et al 2004, and Hagras and Callaghan 2005). Each agent is equipped with sensors and effectors and uses a learning system based on fuzzy logic. A real AmI environment in the form of an "intelligent dormitory" is used for experimentation.

Privacy and security in the context of AmI applications at home, at work, and in the health, shopping and mobility domains are discussed in (Friedewald et al 2007). For such applications they consider security threats such as surveillance of users, identity theft and malicious attacks, as well as the potential of the digital divide amongst communities and social pressures.

AMBIENT INTELLIGENCE FOR INDEPENDENT LIVING

One major use of AmI is to support services for **independent living**, to prolong the time people can live decently in their own homes by increasing their autonomy and self-confidence. This may involve the elimination of monotonous everyday activities, monitoring and caring for the elderly, provision of security, or saving resources. The aim of such AmI applications is to help:

- maintain safety of a person by monitoring his environment and recognizing and anticipating risks, and taking appropriate actions,
- provide assistance in daily activities and requirements, for example, by reminding and advising about medication and nutrition, and
- improve quality of life, for example by providing personalized information about entertainment and social activities.

This area has attracted a great deal of attention in recent years, because of increased longevity and the aging population in many parts of the world. For such an AmI system to be useful and accepted it needs to be versatile, adaptable, capable of dealing with changing environments and situations, transparent and easy, and even pleasant, to interact with.

We believe that it would be promising to explore an approach based on providing an **agent architecture** consisting of a society of heterogeneous, intelligent, **embedded agents**, each specialised in one or more functionalities. The agents should be capable of sharing information through communication, and their dialogues and behaviour should be governed by context-dependent and dynamic norms.

The basic capabilities for intelligent agents include:

- *Sensing*: to allow the agent observe the environment
- *Reactivity*: to provide context-dependent dynamic behaviour and the ability to adapt to changes in the environment
- *Planning*: to provide goal-directed behaviour
- *Goal Decision*: to allow dynamic decisions about which goals have higher priorities

- *Action execution*: to allow the agent to affect the environment.

All of these functionalities also require reasoning about spatio-temporal constraints reflecting the environment in which an AmI system operates.

Most of these functionalities have been integrated in the **KGP model** (Kakas et al, 2004), whose architecture is shown in Figure 2 and implemented in the PROSOCS system (Bracciali et al, 2006). The use of **reactivity** for communication and dialogue policies has also been discussed in, for example, (Sadri et al, 2003). The inclusion of normative behaviour has been discussed in (Sadri et al, 2006) where we also consider how to choose amongst different types of goals, depending on the governing norms. For a general discussion on the importance of norms in artificial societies see (Pitt, 2005).

KGP agents are situated in the environment via their *physical capabilities*. Information received from the environment (including other agents) updates the agents *state* and provides input to its dynamic *cycle theory*, which, in turn, determines the next steps in terms of its *transitions*, using its *reasoning capabilities*.

FUTURE TRENDS

As most other information and communication technologies, AmI is not likely to be good or bad on its own, but its value will be judged from the different

ways the technology will be used to improve people's lives. In this section we discuss new opportunities and challenges for the integration of AmI with what people do in ordinary settings. We abstract away from hardware trends and we focus on areas that are software related and are likely to play an important role in the adoption of AmI technologies.

A focal point is the observation that people discover and understand the world through visual and conversational interactions. As a result, in the coming years we expect to see the design of AmI systems to focus in ways that will allow humans to interact in natural ways, using their common skills such as speaking, gesturing, glancing. This kind of *natural interaction* (Leibe et al 2000) will complement existing interfaces and will require that AmI systems be capable of representing virtual objects, possibly in 3D, as well as capture people's moves in the environment and identify which of these moves are directed to virtual objects.

We also expect to see new research directed towards processing of sensor data with different information (Massaro and Friedman 1990) and different kind of formats such as audio, video, and RFID. Efficient techniques to index, search, and structure these data and ways to transform them to the higher-level semantic information required by cognitive agents will be an important area for future work. Similarly, the reverse of this process is likely to be of equal importance, namely, how to translate high-level information to the lower-level signals required by actuators that are situated in the environment.

Given that sensors and actuators will provide the link with the physical environment, we also anticipate further research to address the general linking of AmI systems to already existing computing infrastructures such as the *semantic web*. This work will create hybrid environments that will need to combine useful information from existing wired technologies with information from wireless ones (Stathis et al 2007). To enable the creation of such environments we imagine the need to build new frameworks and middleware to facilitate integration of heterogeneous AmI systems and make the interoperation more flexible.

Another important issue is how the human experience in AmI will be managed in a way that will be as unobtrusive as possible. In this we foresee that developments in cognitive systems will play a very important role. Although there will be many areas of cognitive system behaviour that will need to be addressed, we

Figure 2. The architecture of a KGP agent

anticipate that development of **agent models** that adapt and learn (Sutton and Barto 1998), to be of great importance. The challenge here will be how to integrate the output of these adaptive and learning capabilities to the reasoning and decision processes of the agent. The resulting cognitive behaviour must differentiate between newly learned concepts and existing ones, as well as discriminate between normal behaviour and exceptions.

We expect that AmI will emerge with the formation of user communities who live and work in a particular locality (Stathis et al 2006). The issue then becomes how to manage all the information that is provided and captured as the system evolves. We foresee research to address issues such as semantic annotations of content, and partitioning and ownership of information.

Linking in local communities with smart homes, e-healthcare, mobile commerce, and transportation systems will eventually give rise to a global AmI system. For applications in such a system to be embraced by people we will need to see specific human factors studies to decide how unobtrusive, acceptable and desirable the actions of the AmI environment seem to people who use them. Some human factors studies should focus on issues of presentation of objects and agents in a 3D setting, as well as on the important issues of privacy, trust and security.

To make possible the customization of system interactions to different classes of users, it is required to acquire and store information about these users. Thus for people to trust AmI interactions in the future we must ensure that the omnipresent intelligent environment maintains privacy in an ethical manner. Ethical or, better, normative behaviour cannot only be ensured at the cognitive level (Sadri et al 2006), but also at the lower, implementation level of the AmI platform. In this context, ensuring that communicated information is encrypted, certified, and follows transparent security policies will be required to build systems less vulnerable to malicious attacks. Finally, we also envisage changes to business models that would characterise AmI interactions (Hax and Wielde 2001).

CONCLUSION

The successful adoption of AmI is predicated on the suitable combination of ubiquitous computing, artificial intelligence and agent technologies. A useful class of

applications that can test such a combination is AmI supporting independent living. For such applications we have identified the trends that are likely to play an important role in the future.

TERMS AND DEFINITIONS

Artificial Societies: Complex systems consisting of a, possibly large, set of agents whose interaction are constrained by norms and the roles the agents are responsible to play.

Cognitive Agents: Software agents endowed with high-level mental attitudes, such as beliefs, goals and plans.

Context Awareness: Refers to the idea that computers can both sense and react according to the state of the environment they are situated. Devices may have information about the circumstances under which they are able to operate and react accordingly.

Natural Interaction: The investigation of the relationships between humans and machines aiming to create interactive artifacts that respect and exploit the natural dynamics through which people communicate and discover the real world.

Smart Homes: Homes equipped with intelligent sensors and devices within a communications infrastructure that allows the various systems and devices to communicate with each other for monitoring and maintenance purposes.

Ubiquitous Computing: A model of human-computer interaction in which information processing is integrated into everyday objects and activities. Unlike the desktop paradigm, in which a single user chooses to interact with a single device for a specialized purpose, with ubiquitous computing a user interacts with many computational devices and systems simultaneously, in the course of ordinary activities, and may not necessarily even be aware that is doing so.

Wireless Sensor Networks: Wireless networks consisting of spatially distributed autonomous devices using sensors to cooperatively monitor physical or environmental conditions, such as temperature, sound, vibration, pressure, motion or pollutants, at different locations.

Ambient Intelligence Environments

Carlos Ramos

Polytechnic of Porto, Portugal

INTRODUCTION

The trend in the direction of hardware cost reduction and miniaturization allows including computing devices in several objects and environments (embedded systems). Ambient Intelligence (AmI) deals with a new world where computing devices are spread everywhere (ubiquity), allowing the human being to interact in physical world environments in an intelligent and unobtrusive way. These environments should be aware of the needs of people, customizing requirements and forecasting behaviours.

AmI environments may be so diverse, such as homes, offices, meeting rooms, schools, hospitals, control centers, transports, touristic attractions, stores, sport installations, and music devices.

Ambient Intelligence involves many different disciplines, like automation (sensors, control, and actuators), human-machine interaction and computer graphics, communication, ubiquitous computing, embedded systems, and, obviously, Artificial Intelligence. In the aims of Artificial Intelligence, research envisages to include more intelligence in the AmI environments, allowing a better support to the human being and the access to the essential knowledge to make better decisions when interacting with these environments.

BACKGROUND

Ambient Intelligence (AmI) is a concept developed by the European Commission's IST Advisory Group ISTAG (ISTAG, 2001)(ISTAG, 2002). ISTAG believes that it is necessary to take a holistic view of Ambient Intelligence, considering not just the technology, but the whole of the innovation supply-chain from science to end-user, and also the various features of the academic, industrial and administrative environment that facilitate or hinder realisation of the AmI vision (ISTAG, 2003). Due to the great amount of technologies involved in the Ambient Intelligence concept we

may find several works that appeared even before the ISTAG vision pointing in the direction of Ambient Intelligence trends.

In what concerns Artificial Intelligence (AI), Ambient Intelligence is a new meaningful step in the evolution of AI (Ramos, 2007). AI has closely walked side-by-side with the evolution of Computer Science and Engineering. The building of the first artificial neural models and hardware, with the Walter Pitts and Warren McCullock work (Pitts & McCullock, 1943) and Marvin Minsky and Dean Edmonds SNARC system correspond to the first step. Computer-based Intelligent Systems, like the MYCIN Expert System (Shortliffe, 1976) or network-based Intelligent Systems, like AUTHORIZER's ASSISTANT (Rothi, 1990) used by American Express for authorizing transactions consulting several Data Bases are the kind of systems of the second step of AI. From the 80's Intelligent Agents and Multi-Agent Systems have established the third step, leading more recently to Ontologies and Semantic Web. From hardware to the computer, from the computer to the local network, from the local network to the Internet, and from the Internet to the Web, Artificial Intelligence was on the state of the art of computing, most of times a little bit ahead of the technology limits.

Now the centre is no more in the hardware, or in the computer, or even in the network. Intelligence must be provided to our daily-used environments. We are aware of the push in the direction of Intelligent Homes, Intelligent Vehicles, Intelligent Transportation Systems, Intelligent Manufacturing Systems, even Intelligent Cities. This is the reason why Ambient Intelligence concept is so important nowadays (Ramos, 2007).

Ambient Intelligence is not possible without Artificial Intelligence. On the other hand, AI researchers must be aware of the need to integrate their techniques with other scientific communities' techniques (e.g. Automation, Computer Graphics, Communications). Ambient Intelligence is a tremendous challenge, needing the better effort of different scientific communities.

There is a miscellaneous of concepts and technologies related with Ambient Intelligence. Ubiquitous Computing, Pervasive Computing, Embedded Systems, and Context Awareness are the most common. However these concepts are different from Ambient Intelligence.

The concept of Ubiquitous Computing (UbiComp) was introduced by Mark Weiser during his tenure as Chief Technologist of the Palo Alto Research Center (PARC) (Weiser, 1991). Ubiquitous Computing means that we have access to computing devices anywhere in an integrated and coherent way. Ubiquitous Computing was mainly driven by Communications and Computing devices scientific communities but now is involving other research areas. Ambient Intelligence differs from Ubiquitous Computing because sometimes the environment where Ambient Intelligence is considered is simply local. Another difference is that Ambient Intelligence makes more emphasis on intelligence than Ubiquitous Computing. However, ubiquity is a real need today and Ambient Intelligence systems are considering this feature.

A concept that sometimes is seen as a synonymous of Ubiquitous Computing is Pervasive Computing. According to Teresa Dillon, Ubiquitous Computing is best considered as the underlying framework, the embedded systems, networks and displays which are invisible and everywhere, allowing us to 'plug-and-play' devices and tools. On the other hand, Pervasive Computing, is related with all the physical parts of our lives; mobile phone, hand-held computer or smart jacket (Dillon, 2006).

Embedded Systems mean that electronic and computing devices are embedded in current objects or goods. Today goods like cars are equipped with microprocessors; the same is true for washing machines, refrigerators, and toys. Embedded Systems community is more driven by electronics and automation scientific communities. Current efforts go in the direction to include electronic and computing devices in the most usual and simple objects we use, like furniture or mirrors. Ambient Intelligence differs from Embedded Systems since computing devices may be clearly visible in Aml scenarios. However, there is a clear trend to involve more embedded systems in Ambient Intelligence.

Context Awareness means that the system is aware of the current situation we are dealing with. An example is the automatic detection of the current situation in a Control Centre. Are we in presence of a normal situation

or are we dealing with a critical situation, or even an emergency? In this Control Centre the intelligent alarm processor will exhibit different outputs according to the identified situation (Vale, Moura, Fernandes, Marques, Rosado, Ramos, 1997). Automobile Industry is also investing in Context Aware systems, like near-accident detection. Human-Computer Interaction scientific community is paying lots of attention to Context Awareness. Context Awareness is one of the most desired concepts to include in Ambient Intelligence, the identification of the context is important for deciding to act in an intelligent way.

There are different views of the importance of other concepts and technologies in the Ambient Intelligence field. Usually these differences are derived from the basic scientific community of the authors. ISTAG see the technology research requirements from different points of view (Components, Integration, System, and User/Person). In (ISTAG, 2003) the following ambient components are mentioned: smart materials; MEMS and sensor technologies; embedded systems; ubiquitous communications; I/O device technology; adaptive software. In the same document ISTAG refers the following intelligence components: media management and handling; natural interaction; computational intelligence; context awareness; and emotional computing.

Recently Ambient Intelligence is receiving a significant attention from Artificial Intelligence Community. We may refer the Ambient Intelligence Workshops organized by Juan Augusto and Daniel Shapiro at ECAI'2006 (European Conference on Artificial Intelligence) and IJCAI'2007 (International Joint Conference on Artificial Intelligence) and the Special Issue on Ambient Intelligence, coordinated by Carlos Ramos, Juan Augusto and Daniel Shapiro to appear in the March/April'2008 issue of the IEEE Intelligent Systems magazine.

AMBIENT INTELLIGENT PROTOTYPES AND SYSTEMS

Here we will analyse some examples of Ambient Intelligence prototypes and systems, divided by the area of application.

Aml at Home

Domotics is a consolidated area of activity. After the first experiences using Domotics at homes there was a trend to refer the Intelligent Home concept. However, Domotics is too centred in the automation, giving to the user the capability to control the house devices from everywhere. We are still far from the real Ambient Intelligence in homes, at least at the commercial level. In (Wichert, Hellschmidt, 2006) there is an interesting example in the aims of EMBASSI project, by gesture a woman is commanding the TV to be brighter, however the TV is already at the brightest level, so the lights reduce the level and the windows close, showing an example of context awareness in the environment.

Several organizations are doing experiments to achieve the Intelligent Home concept. Some examples are HomeLab from Philips, MIT House_n, Georgia Tech Aware Home, Microsoft Concept Home, and e2 Home from Electrolux and Ericsson.

Aml in Vehicles and Transports

Since the first experiences with NAVLAB 1 (Thorpe, Herbert, Kanade, Shafer, 1988) Carnegie Mellon University has developed several prototypes for Autonomous Vehicle Driving and Assistance. The last one, NAVLAB 11, is an autonomous Jeep. Most of the car industry companies are doing research in the area of Intelligent Vehicles for several tasks like car parking assistance or pre-collision detection.

Another example of Aml application is related with Transports, namely in connection with Intelligent Transportation Systems (ITS). The ITS Joint Program of the US Department of Transportation identified several areas of applications, namely: arterial management; freeway management; transit management; incident management; emergence management; electronic payment; traveller information; information management; crash prevention and safety; roadway operations and management; road weather management; commercial vehicle operations; and intermodal freight. In all these application areas Ambient Intelligence can be used.

Aml in Elderly and Health Care

Several studies point to the aging of population during the next decades. While being a good result of increasing of life expectation, this also implies some

problems. The percentage of population with health problems will increase and it will be very difficult to Hospitals to maintain all patients. Our society is faced with the responsibility to care for these people in the best possible social and economical ways. So, there is a clear interest to create Ambient Intelligence devices and environments allowing the patients to be followed in their own homes or during their day-by-day life.

The medical control support devices may be embedded in clothes, like T-shirts, collecting vital-sign information from sensors (e. g. blood pressure, temperature). Patients will be monitored at long distance. The surrounding environment, for example the patient home, may be aware of the results from the clinical data and even perform emergency calls to order an ambulance service.

For instance, we may refer the IST Vivago® system (IST International Security Technology Oy, Helsinki, Finland), an active social alarm system, which combines intelligent social alarms with continuous remote monitoring of the user's activity profile (Särelä, Korhonen, Lötjönen, Sola, Myllymäki, 2003).

Aml in Tourism and Cultural Heritage

Tourism and Cultural Heritage are good application areas for Ambient Intelligence. Tourism is a growing industry. In the past tourists were satisfied with pre-defined tours, equal for all the people. However there is a trend in the customization and the same tour can be conceived to adapt to tourists according their preferences.

Immersive tour post is an example of such experience (Park, Nam, Shi, Golub, Van Loan, 2006). MEGA is an user-friend virtual-guide to assist visitors in the Parco Archeologico della Valle del Temple in Agrigento, an archaeological area with ancient Greek temples in Agrigento, located in Sicily, Italy (Pilato, Augello, Santangelo, Gentile, Gaglio, 2006). DALICA has been used for constructing and updating the user profile of visitors of Villa Adriana in Tivoli, near Rome, Italy (Constantini, Inverardi, Mostarda, Tocchio, Tsintza, 2007).

Aml at Work

The human being spends considerable time in working places like offices, meeting rooms, manufacturing plants, control centres.

SPARSE is a project initially created for helping Power Systems Control Centre Operators in the diagnosis and restoration of incidents (Vale, Moura, Fernandes, Marques, Rosado, Ramos, 1997). It is a good example of context awareness since the developed system is aware of the on-going situation, acting in different ways according the normal or critical situation of the power system. This system is evolving for an Ambient Intelligence framework applied to Control Centres.

Decision Making is one of the most important activities of the human being. Nowadays decisions imply to consider many different points of view, so decisions are commonly taken by formal or informal groups of persons. Groups exchange ideas or engage in a process of argumentation and counter-argumentation, negotiate, cooperate, collaborate or even discuss techniques and/or methodologies for problem solving. Group Decision Making is a social activity in which the discussion and results consider a combination of rational and emotional aspects. ArgEmotionAgents is a project in the area of the application of Ambient Intelligence in the group argumentation and decision support considering emotional aspects and running in the Laboratory of Ambient Intelligence for Decision Support (LAID), seen in Figure 1 (Marreiros, Santos, Ramos, Neves, Novais, Machado, Bulas-Cruz, 2007), a kind of an Intelligent Decision Room. This work has also a part involving ubiquity support.

Aml in Sports

Sports involve high-level athletes and many more practitioners. Many sports are done without any help of the associated devices, opening here a clear opportunity for Ambient Intelligence to create sports assistance devices and environments.

FlyMaster NAV+ is a free-flight on-board pilot Assistant (e.g. gliding, paragliding), using the FlyMaster F1 module with access to GPS and sensorial information. FlyMaster Avionics S.A., a spin-off, was created to commercialize these products (see figure 2).

AMBIENT INTELLIGENCE PLATFORMS

Some companies and academic institutions are investing in the creation of Ambient Intelligence generation platforms.

The Endeavour project is developed by the California University in Berkeley (<http://endeavour.cs.berkeley.edu/>). The project aims to specify, design, and implement prototypes at a planet scale, self organized and involving an adaptive “Information Utility”.

Oxygen enables pervasive human centred computing through a combination of specific user and system technologies (<http://www.oxygen.lcs.mit.edu/>). This project provides speech and vision technologies enabling us to communicate with Oxygen as if we were interacting with another person, saving much time and effort (Rudolph, 2001).

The Portolano project was developed in the University of Washington and seeks to create a testbed for research into the emerging field of invisible computing (<http://portolano.cs.washington.edu/>). The invisible computing is possible with devices so highly optimized to particular tasks that they bend into the world and require little technical knowledge from the users (Esler, Hightower, Anderson, Borriello, 1999).

The EasyLiving project of Microsoft Research Vision Group corresponds to a prototype architecture and associated technologies for building intelligent environments (Brumitt, Meyers, Krumm, Kern, Shafer,

Figure 1. Ambient Intelligence for decision support, LAID Laboratory

Figure 2. FlyMaster Pilot Assistant device, from FlyMaster Avionics S.A.

2000). EasyLiving goal is to facilitate the interaction of people with other people, with computer, and with devices (<http://research.microsoft.com/easyliving/>).

FUTURE TRENDS

Ambient Intelligence deals with a futuristic notion for our lives. Most of the practical experiences concerning Ambient Intelligence are still in a very incipient phase, due to the recent existence of this concept. Today, it is not clear the separation between the computer and the environments. However, for new generations things will be more transparent, and environments with Ambient Intelligence will be more widely accepted.

In the area of transport, AmI will cover several aspects. The first will be related with the vehicle itself. Several performances start to be available, like the automatic identification of the situation (e.g. pre-collision identification, identification of the driver conditions). Other aspects will be related with the traffic information. Today, GPS devices are generalized, but they deal with static information. Joining on-line traffic conditions will enable the driver to avoid roads with accidents. Technology is giving good steps in the direction of automatic vehicle driving. But in the near future the developed systems will be seen more like driver assistants in spite of autonomous driving systems.

Another area where AmI will experience a strong development will be the area of Health Care, especially

in the Elderly Care. Patients will receive this support to allow a more autonomous life in their homes. However automatic acquisition of vital signals (e.g. blood pressure, temperature) will allow to do automatic emergency calls when the patient health is in significant trouble. The person monitoring will also be done in his/her home, trying to detect differences in expected situations and habits.

The home support will achieve the normal personal and family life. Intelligent Homes will be a reality. The home residents will pay less attention to normal home management aspects, for example, how many bottles of red wine are available for the week meals or if the specific ingredients for a cake are all available.

AmI for job support are also expected. Decision Support Systems will be oriented to on-the-job environments. This will be clear in offices, meeting rooms, call centres, control centres, and plants.

CONCLUSION

This article presents the state of the art in which concerns Ambient Intelligence field. After the history of the concept, we established some related concepts definitions and illustrated with some examples. There is a long way to follow in order to achieve the Ambient Intelligence concept, however in the future, this concept will be referred as one of the landmarks in the Artificial Intelligence development.

TERMS AND DEFINITIONS

Ambient Intelligence: Ambient Intelligence (AmI) deals with a new world where computing devices are spread everywhere, allowing the human being to interact in physical world environments in an intelligent and unobtrusive way. These environments should be aware of the needs of people, customizing requirements and forecasting behaviours.

Context Awareness: Context Awareness means that the system is aware of the current situation we are dealing with.

Embedded Systems: Embedded Systems means that electronic and computing devices are embedded in current objects or goods.

Intelligent Decision Room: A decision-making space, eg a meeting room or a control center, equipped with intelligent devices and/or systems to support decision-making processes.

Intelligent Home: A home equipped with several electronic and interactive devices to help residents to manage conventional home decisions.

Intelligent Transportation Systems: Intelligent Systems applied to the area of Transports, namely to traffic and travelling issues.

Intelligent Vehicles: A vehicle equipped with sensors and decision support components.

Pervasive Computing: Pervasive Computing is related with all the physical parts of our lives, the user may have not notion of the computing devices and details related with these physical parts.

Ubiquitous Computing: Ubiquitous Computing means that we have access to computing devices anywhere in an integrated and coherent way.

Analytics for Noisy Unstructured Text Data I

A

INTRODUCTION

Accdrnig to rscheearch at Cmabrigde Uinervtisy, it deosn't mtttaer in what oredr the ltteers in a wrod are, the only iprmoetnt tihng is that the frist and lsat ltteer be at the rghit pclae. Tihs is bcuseae the human mnid deos not raed ervey lteter by istlef, but the wrod as a wlohe.¹

Unfortunately computing systems are not yet as smart as the human mind. Over the last couple of years a significant number of researchers have been focusing on noisy text analytics. Noisy text data is found in informal settings (online chat, SMS, e-mails, message boards, among others) and in text produced through automated speech recognition or optical character recognition systems. Noise can possibly degrade the performance of other information processing algorithms such as classification, clustering, summarization and information extraction. We will identify some of the key research areas for noisy text and give a brief overview of the state of the art. These areas will be, (i) classification of noisy text, (ii) correcting noisy text, (iii) information extraction from noisy text. We will cover the first one in this chapter and the later two in the next chapter.

We define *noise* in text as any kind of difference in the surface form of an electronic text from the intended, correct or original text. We see such *noisy text* everyday in various forms. Each of them has unique characteristics and hence requires special handling. We introduce some such forms of noisy textual data in this section.

Online Noisy Documents: E-mails, chat logs, scrap-book entries, newsgroup postings, threads in discussion fora, blogs, etc., fall under this category. People are typically less careful about the sanity of written content in such informal modes of communication. These are characterized by frequent misspellings, commonly

and not so commonly used abbreviations, incomplete sentences, missing punctuations and so on. Almost always noisy documents are human interpretable, if not by everyone, at least by intended readers.

SMS: Short Message Services are becoming more and more common. Language usage over SMS text significantly differs from the standard form of the language. An urge towards shorter message length facilitating faster typing and the need for semantic clarity, shape the structure of this non-standard form known as the *texting language* (Choudhury et. al., 2007).

Text Generated by ASR Devices: ASR is the process of converting a speech signal to a sequence of words. An ASR system takes speech signal such as monologs, discussions between people, telephonic conversations, etc. as input and produces a string of words, typically not demarcated by punctuations as *transcripts*. An ASR system consists of an acoustic model, a language model and a decoding algorithm. The acoustic model is trained on speech data and their corresponding manual transcripts. The language model is trained on a large monolingual corpus. ASR convert audio into text by searching the acoustic model and language model space using the decoding algorithm. Most conversations at contact centers today between agents and customers are recorded. To do any processing of this data to obtain customer intelligence it is necessary to convert the audio into text.

Text Generated by OCR Devices: Optical character recognition, or 'OCR', is a technology that allows digital images of typed or handwritten text to be transferred into an editable text document. It takes the picture of text and translates the text into Unicode or ASCII. . For handwritten optical character recognition, the rate of recognition is 80% to 90% with clean handwriting.

Call Logs in Contact Centers: Today's contact centers (also known as call centers, BPOs, KPOs) produce huge amounts of unstructured data in the form of call logs apart from emails, call transcriptions, SMS, chat

transcripts etc. Agents are expected to summarize an interaction as soon as they are done with it and before picking up the next one. As the agents work under immense time pressure hence the summary logs are very poorly written and sometimes even difficult for human interpretation. Analysis of such call logs are important to identify problem areas, agent performance, evolving problems etc.

In this chapter we will be focussing on automatic classification of noisy text. Automatic text classification refers to segregating documents into different topics depending on content. For example, categorizing customer emails according to topics such as billing problem, address change, product enquiry etc. It has important applications in the field of email categorization, building and maintaining web directories e.g. DMoz, spam filter, automatic call and email routing in contact center, pornographic material filter and so on.

NOISY TEXT CATEGORIZATION

The text classification task is one of the learning models for a given set of classes and applying these models to new unseen documents for class assignment. This is an important component in many knowledge extraction tasks; real time sorting of email or files into folder hierarchies, topic identification to support topic-specific processing operations, structured search and/or browsing, or finding documents corresponding to long-term standing interests or more dynamic task-based interests. Two types of classifiers are generally commonly found viz. *statistical classifiers* and *rule based classifiers*.

In statistical techniques a *model* is typically trained on a corpus of labelled data and once trained the system can be used for automatic assignment of unseen data. A survey of text classification can be found in the work by Aas & Eikvil (Aas & Eikvil, 1999). Given a training document collection $\mathcal{D} = \{d_1, d_2, \dots, d_M\}$ with true classes $\{y_1, y_2, \dots, y_M\}$ the task is to learn a *model*. This model is used for categorizing a new unlabelled document d_u . Typically words appearing in the text are used as features. Other applications including search rely heavily on taking the markup or link structure of documents into account but classifiers only depend on the content of the documents or the collection of words present in the documents. Once features are extracted

from documents, each document is converted into a document vector. Documents are represented in a vector space; each dimension of this space represents a single feature and the importance of that feature in that document gives the exact distance from the origin. The simplest representation of document vectors uses the binary event model, where if a feature $j \in V$ appears in document d_i , then the j^{th} component of d_i is 1 otherwise it is 0. One of the most popular statistical classification techniques is naive Bayes (McCallum, 1998). In the naive Bayes technique the probability of a document d_i belonging to class c is computed as:

$$\begin{aligned} \Pr(c | d) &= \frac{\Pr(c, d)}{\Pr(d)} \\ &= \frac{\Pr(c) \Pr(d | c)}{\Pr(d)} \\ &\propto \Pr(c) \Pr(d | c) \end{aligned}$$

$$\propto \prod_j P(d_j | c)$$

The final approximation of the above equation refers to the naive part of such a model, i.e., the assumption of word independence which means the features are assumed to be conditionally independent, given the class variable.

Rule-based learning systems have been adopted in the document classification problem since it has considerable appeal. They perform well at finding simple axis-parallel frontiers. A typical rule-based classification scheme for a category, say C , has the form:

Assign category C if antecedent or
Do no assign category C if antecedent or

The antecedent in the premise of a rule usually involves some kind of feature value comparison. A rule is said to cover a document or a document is said to satisfy a rule if all the feature value comparisons in the antecedent of the rule are true for the document. One of the well known works in the rule based text classification domain is RIPPER. Like a standard separate-and-conquer algorithm, it builds a rule set incrementally. When a rule is found, all documents covered by the rule are discarded including positive

and negative documents. The rule is then added to the rule set. The remaining documents are used to build other rules in the next iteration.

In both statistical as well as rule based text classification techniques, the content of the text is the sole determiner of the category to be assigned. However noise in the text distorts the content and hence readers can expect the categorization performance to get affected by noise in the text. Classifiers are essentially trained to identify correlation between extracted features (words) with different categories which can be later utilized to categorize new documents. For example, words like *exciting offer get a free laptop* might have stronger correlation with category *spam emails* than non-spam emails. Noise in text distorts this feature space *excitinnng ofer get frree lap top* will be new set of features and the categorizer will not be able to relate it to the *spam emails* category. The feature space explodes as the same feature can appear in different forms due to spelling errors, poor recognition, wrong transcription, etc. In the remaining part of this section we will give an overview how people have approached the problem of categorizing noisy text.

Categorization of OCRRed Documents

Electronically recognized handwritten documents and documents generated from OCR process are typical examples of noisy text because of the errors introduced by the recognition process. Vinciarelli (Vinciarelli, 2004) has studied the characteristics of noise present in such data and its effects on categorization accuracy. A subset of documents from the Reuters-21578 text classification dataset were taken and noise was introduced using two methods: first a subset of documents were manually written and recognized using an offline handwriting recognition system. In the second the OCR based extraction process was simulated by randomly changing a certain percentage of characters. According to them for recall values up to 60-70 percent depending on the sources, the categorization system is robust to noise even when the Term Error Rate is higher than 40 percent. It was also observed that the results from the handwritten data appeared to be lower than those obtained from OCR simulations. Generic systems for text categorization based on statistical analysis of representative text corpora have been proposed (Bayer et. al., 1998). Features are extracted from training texts by selecting substrings from actual word forms and

applying statistical information and general linguistic knowledge followed by dimensionality reduction by linear transformation. The actual categorization system is based on minimum least-squares approach. The system is evaluated on the tasks of categorizing abstracts of paper-based German technical reports and business letters concerning complaints. Approximately 80% classification accuracy is obtained and it is seen that the system is very robust against recognition or typing errors.

Issues with categorizing OCRRed documents are also discussed by many other authors (Brooks & Teahan, 2007), (Hoch, 1994) and (Taghva et. al., 2001).

Categorization of ASRed Documents

Automatic Speech Recognition (ASR) is simply the process of converting an acoustic signal to a sequence of words. Researchers have proposed different techniques for speech recognition tasks based on Hidden Markov model (HMM), neural networks, Dynamic time warping (DTW) (Trentin & Gori, 2001). The performance of an ASR system is typically measured in terms of Word Error Rate (WER), which is derived from the Levenshtein distance, working at word level instead of character. WER can be computed as

$$WER = \frac{S + D + I}{N}$$

where S is the number of substitutions, D is the number of the deletions, I is the number of the insertions, and N is the number of words in the reference. Bahl et.al. (Bahl et. al. 1995) have built an ASR system and demonstrated its capability on benchmark datasets.

ASR systems give rise to word substitutions, deletions and insertions, while OCR systems produce essentially word substitutions. Moreover, ASR systems are constrained by a lexicon and can give as output only words belonging to it, while OCR systems can work without a lexicon (this corresponds to the possibility of transcribing any character string) and can output sequences of symbols not necessarily corresponding to actual words. Such differences are expected to have strong influence on performance of systems designed for categorizing ASRed documents in comparison to categorization of OCRRed documents. A lot of work on automatic call type classification for the purpose of

categorizing calls (Tang et al., 2003), call routing (Kuo and Lee, 2003; Haffner et al., 2003), obtaining call log summaries (Douglas et al., 2005), agent assisting and monitoring (Mishne et al., 2005) has appeared in the past. Here calls are classified based on the transcription from an ASR system. One interesting work on seeing effect of ASR noise on text classification was done on a subset of benchmark text classification dataset Reuters-21578² (Agarwal et al., 2007). They read out and automatically transcribed 200 documents and applied a text classifier trained on clean Reuters-21578 training corpus³. Surprisingly, in spite of high degree of noise, they did not observe much degradation in accuracy.

Effect of Spelling Errors on Categorization

Spelling errors are an integral part of written text—electronic as well as non-electronic. Every reader reading this book must have been scolded by their teacher in school for spelling words wrongly! In this era of electronic text people have become less careful while writing resulting poorly written text containing abbreviations, short forms, acronyms, wrong spellings. Such electronic text documents including email, chat log, postings, SMSs are sometimes difficult to interpret even for human beings. It goes without saying that text analytics on such noisy data is a non trivial task.

Wrong spellings can affect automatic classification performance in multiple ways depending on the nature of the classification technique being used. In the case of statistical techniques, spelling differences distort the feature space. If training as well as the test data corpus are noisy, while learning the model the classifier will treat variants of the same words as different features. As a result the observed joint probability distribution will be different from the actual distribution. If the proportion of wrongly spelt words is high then the distortion can be significant and will hurt the accuracy of the resultant classifier. However, if the classifier is trained on a clean corpus and the test documents are noisy, then wrongly spelt words will be treated as unseen words and will not help in classification. In an unlikely situation a wrongly spelt word present in a test document may become a different valid feature and worse, may become a valid indicative feature of a different class. A standard technique in the text classification process is *feature selection* which happens after *feature extraction* and before *training*. Feature

selection typically employs some statistical measures over the training corpus and ranks features in order of the amount of information (correlation) they have with respect to the class labels of the classification task at hand. After the feature set has been ranked, the top few features are retained (typically order of hundreds or a few thousand) and the others are discarded. Feature selection should be able to eliminate wrongly spelt words present in the training data provided (i) the proportion of wrongly spelt words is not very large and (ii) there is no regular pattern in spelling errors⁴. However it has been observed, even at high degree of spelling errors the classification accuracy does not suffer much (Agarwal et al., 2007).

Rule based classification techniques also get negatively affected by spelling errors. If the training data contains spelling errors then some of the rules may not get the required statistical significance. Due to spelling errors present in the test data a valid rule may not fire and worse, an invalid rule may fire leading to a wrong categorization. Suppose RIPPER has learnt a rule set like:

Assign category “sports” IF
(the document contains {it sports}) OR
(the document contains {it exercise} AND {it outdoor}) OR
(the document contains {it exercise} but not {it homework} {it exam}) OR
(the document contains {it play} AND {it rule}) OR

A hypothetical test document containing repeated occurrences of *exercise*, but each time wrongly spelt as *exarcise*, will not be categorized to the *sports* category and hence lead to misclassification.

CONCLUSION

In this chapter we have looked at noisy text analytics. This topic is gaining in importance as more and more noisy data gets generated and needs processing. In particular we have looked at techniques for correcting noisy text and for doing classification. We have presented a survey of existing techniques in the area and have shown that even though it is a difficult problem it is possible to address it with a combination of new and existing techniques.

KEY TERMS

Automatic Speech Recognition: Machine recognition and conversion of spoken words into text.

Data Mining: The application of analytical methods and tools to data for the purpose of identifying patterns, relationships or obtaining systems that perform useful tasks such as classification, prediction, estimation, or affinity grouping.

Information Extraction: Automatic extraction of structured knowledge from unstructured documents.

Noisy Text: Text with any kind of difference in the surface form, from the intended, correct or original text.

Optical Character Recognition: Translation of images of handwritten or typewritten text (usually captured by a scanner) into machine-editable text.

Rule Induction: Process of learning, from cases or instances, if-then rule relationships that consist of an antecedent (if-part, defining the preconditions or coverage of the rule) and a consequent (then-part, stating a classification, prediction, or other expression of a property that holds for cases defined in the antecedent).

Text Analytics: The process of extracting useful and structured knowledge from unstructured documents to find useful associations and insights.

Text Classification (or Text Categorization): Is the task of learning models for a given set of classes and applying these models to new unseen documents for class assignment.

Analytics for Noisy Unstructured Text Data II

L. Venkata Subramaniam

IBM Research, India Research Lab, India

Shourya Roy

IBM Research, India Research Lab, India

INTRODUCTION

The importance of text mining applications is growing proportionally with the exponential growth of electronic text. Along with the growth of internet many other sources of electronic text have become really popular. With increasing penetration of internet, many forms of communication and interaction such as email, chat, newsgroups, blogs, discussion groups, scraps etc. have become increasingly popular. These generate huge amount of noisy text data everyday. Apart from these the other big contributors in the pool of electronic text documents are call centres and customer relationship management organizations in the form of call logs, call transcriptions, problem tickets, complaint emails etc., electronic text generated by Optical Character Recognition (OCR) process from hand written and printed documents and mobile text such as Short Message Service (SMS). Though the nature of each of these documents is different but there is a common thread between all of these—presence of noise.

An example of information extraction is the extraction of instances of corporate mergers, more formally *MergerBetween(company1,company2,date)*, from an online news sentence such as: “*Yesterday, New-York based Foo Inc. announced their acquisition of Bar Corp.*” *Opinion(product1,good)*, from a blog post such as: “*I absolutely liked the texture of SheetK quilts.*”

At superficial level, there are two ways for information extraction from noisy text. The first one is cleaning text by removing noise and then applying existing state of the art techniques for information extraction. There in lies the importance of techniques for automatically correcting noisy text. In this chapter, first we will review some work in the area of noisy text correction. The second approach is to devise extraction techniques which are robust with respect to noise. Later in this chapter,

we will see how the task of information extraction is affected by noise.

NOISY TEXT CORRECTION

Before moving on to techniques for processing noisy text we will briefly introduce methods for correcting noisy text. One of the most common forms of noise in text is wrong spelling. Kukich provides a comprehensive survey of techniques pertaining to detecting and correcting spelling errors (Kukich, 1992). According to this survey, three types of nonword misspellings are typically found viz. **typographic** such as *teh*, *speed*, **cognitive** such as *recieve*, *conspereacy* and **phonetic** such as *abiss*, *nacherly*. A distinction must be made between automatically *detecting* such errors and automatically *correcting* those errors. The latter is a much harder problem. Most of the recent work in this area is about correcting spelling mistakes automatically. Golding and Roth (Golding & Roth, 1999) proposed a combination of a variant of *Winnnow*, a multiplicative weight-update algorithm and weighted majority voting for context sensitive spelling correction. Mangu and Brill (Mangu & Brill, 1997) have shown that a small set of human understandable rules is more meaningful than a large set of opaque features and weights. Hybrid methods capturing the context using trigrams of the parts-of-speech tags and a feature based method have also been proposed to handle context sensitive spelling correction (Golding & Schabes, 1996). There is a lot of work related to automatic correction of spelling errors (Agirre et. al., 1998), (Zamora et. al., 1983), (Golding, 1995). A complete bibliography of all the work related to spelling error detection and correction can be found in (Beebe, 2005). On a related note, automatic spelling error correction techniques have been applied for other

applications such as semantic role labelling (Sang et. al., 2005).

There is also recent work on correcting the output of SMS text (Aw et. al., 2006) (Choudhury et. al., 2007), OCR errors (Nartker et. al., 2003) and ASR errors (Sarma & Palmer, 2004).

INFORMATION EXTRACTION FROM NOISY TEXT

The goal of Information Extraction (IE) is to automatically extract structured information from the unstructured documents. The extracted structured information has to be contextually and semantically well-defined data from a given domain. A typical application of IE is to scan a set of documents written in natural language and populate a database with the information extracted. The MUC (Message Understanding Conference) conference was one effort at codifying the IE task and expanding it (Chinchor, 1998).

There are two basic approaches to the design of IE systems. One comprises the *knowledge engineering approach* where a domain expert writes a set of rules to extract the sought after information. Typically the process of building the system is iterative whereby a set of rules is written, the system is run and the output examined to see how the system is performing. The domain expert then modifies the rules to overcome any under- or over-generation in the output. The second is the *automatic training approach*. This approach is similar to classification where the texts are appropriately annotated with the information being extracted. For example, if we would like to build a city name extractor, then the training set would include documents with all the city names marked. An IE system would be trained on this annotated corpus to learn the patterns that would help in extracting the necessary entities.

An information extraction system typically consists of natural language processing steps such as morphological processing, lexical processing and syntactic analysis. These include stemming to reduce inflected forms of words to their stem, parts of speech tagging to assign labels such as noun, verb, etc. to each word and parsing to determine the grammatical structure of sentences.

Named Entity Annotation of Web Posts

Extraction of named entities is a key IE task. It seeks to locate and classify atomic elements in the text into predefined categories such as the names of persons, organizations, locations, expressions of times, quantities, monetary values, percentages, etc. Entity recognition systems either use rule based techniques or statistical models. Typically a parser or a parts of speech tagger identifies elements such as nouns, noun phrases, or pronouns. These elements along with surface forms of the text are used to define templates for extracting the named entities. For example, to tag company names it would be desirable to look at noun phrases that contain the words *company* or *incorporated* in them. These rules can be automatically learnt using a tagged corpus or could be defined manually. Most known approaches do this on clean well formed text. However, named entity annotation of web posts such as online classifieds, product listings etc. is harder because these texts are not grammatical or well written. In such cases reference sets have been used to annotate parts of the posts (Michelson & Knoblock, 2005). The reference set is thought of as a relational set of data with a defined schema and consistent attribute values. Posts are now matched to their nearest records in the reference set. In the biological domain gene name annotation, even though it is performed on well written scientific articles, can be thought of in the context of noise, because many gene names overlap with common English words or biomedical terms. There have been studies on the performance of the gene name annotator when trained on noisy data (Vlachos, 2006).

Information Extraction from OCR'd Documents

Documents obtained from OCR may have not only unknown words and compound words, but also incorrect words due to OCR errors. In their work Miller et. al. (Miller et. al., 2000) have measured the effect of OCR noise on IE performance. Many IE methods work directly on the document image to avoid errors resulting from converting to text. They adopt keyword matching by searching for string patterns and then use global document models consisting of keyword models and their logical relationships to achieve robustness in matching (Lu & Tan, 2004). The presence of OCR errors has a detrimental effect on information access

from these documents (Taghva et. al., 2004). However, post processing of these documents to correct these errors exist and have been shown to give large improvements.

Information Extraction from ASRed Documents

The output of an ASR system does not contain case information and punctuations. It has been shown that in the absence of punctuations extraction of different syntactic entities like parts of speech and noun phrases is not accurate (Nasukawa et. al., 2007). So IE from ASRed documents becomes harder. Miller et. al. (Miller et. al., 2000) have shown how IE performance varies with ASR noise. It has been shown that it is possible to build aggregate models from ASR data (Roy & Subramaniam, 2006). In this work topical models are constructed by utilizing inter document redundancy to overcome the noise. In this work only a few natural language processing steps have been used. Phrases have been aggregated over the noisy collection to get to the clean underlying text.

FUTURE TRENDS

More and more data from sources like chat, conversations, blogs, discussion groups need to be mined to capture opinions, trends, issues and opportunities. These forms of communication encourage informal language which can be considered noisy due to spelling errors, grammatical errors and informal writing styles. Companies are interested in mining such data to observe customer preferences and improve customer satisfaction. Online agents need to be able to understand web posts to take actions and communicate with other agents. Customers are interested in collated product reviews from web posts of other users. The nature of the noisy text warrants moving beyond traditional text analytics techniques. There is need for developing natural language processing techniques that are robust to noise. Also techniques that implicitly and explicitly tackle textual noise need to be developed.

CONCLUSION

In this chapter we have looked at information extraction from noisy text. This topic is gaining in importance as more and more noisy data gets generated and useful information needs to be obtained from this. We have presented a survey of existing techniques information extraction techniques. We have also presented some of the future trends in noisy text analytics.

KEY TERMS

Automatic Speech Recognition: Machine recognition and conversion of spoken words into text.

Data Mining: The application of analytical methods and tools to data for the purpose of identifying patterns, relationships or obtaining systems that perform useful tasks such as classification, prediction, estimation, or affinity grouping.

Information Extraction: Automatic extraction of structured knowledge from unstructured documents.

Knowledge Extraction: Explication of the internal knowledge of a system or set of data in a way that is easily interpretable by the user.

Noisy Text: Text with any kind of difference in the surface form, from the intended, correct or original text.

Optical Character Recognition: Translation of images of handwritten or typewritten text (usually captured by a scanner) into machine-editable text.

Rule Induction: Process of learning, from cases or instances, if-then rule relationships that consist of an antecedent (if-part, defining the preconditions or

coverage of the rule) and a consequent (then-part, stating a classification, prediction, or other expression of a property that holds for cases defined in the antecedent).

Text Analytics: The process of extracting useful and structured knowledge from unstructured documents to find useful associations and insights.

Angiographic Images Segmentation Techniques

INTRODUCTION

Heart-related pathologies are among the most frequent health problems in western society. Symptoms that point towards cardiovascular diseases are usually diagnosed with **angiographies**, which allow the medical expert to observe the bloodflow in the coronary arteries and detect severe narrowing (**stenosis**). According to the severity, extension, and location of these narrowings, the expert pronounces a diagnosis, defines a treatment, and establishes a prognosis.

The current *modus operandi* is for clinical experts to observe the image sequences and take decisions on the basis of their empirical knowledge. Various techniques and **segmentation** strategies now aim at objectivizing this process by extracting quantitative and qualitative information from the **angiographies**.

BACKGROUND

Segmentation is the process that divides an image in its constituting parts or objects. In the present context, it consists in separating the pixels that compose the coronary tree from the remaining “background” pixels.

None of the currently applied **segmentation** methods is able to completely and perfectly extract the vasculature of the heart, because the images present complex morphologies and their background is inhomogeneous due to the presence of other anatomic elements and artifacts such as catheters.

The literature presents a wide array of coronary tree extraction methods: some apply pattern recognition

techniques based on pure intensity, such as **thresholding** followed by an analysis of connected components, whereas others apply explicit vessel models to extract the vessel contours.

Depending on the quality and noise of the image, some **segmentation** methods may require image pre-processing prior to the **segmentation** algorithm; others may need postprocessing operations to eliminate the effects of a possible oversegmentation.

The techniques and algorithms for vascular **segmentation** could be categorized as follows (Kirbas, Quek, 2004):

1. Techniques for “pattern-matching” or pattern recognition
2. Techniques based on models
3. Techniques based on tracking
4. Techniques based on artificial intelligence
5. Main Focus

This section describes the main features of the most commonly accepted coronary tree **segmentation** techniques. These techniques automatically detect objects and their characteristics, which is an easy and immediate task for humans, but an extremely complex process for artificial computational systems.

Techniques Based on Pattern Recognition

The pattern recognition approaches can be classified into four major categories:

Figure 1. Regions growth applied to an angiography

A

Multiscale Methods

The multiscale method extracts the vessel method by means of images of varying resolutions. The main advantage of this technique resides in its high speed. Larger structures such as main arteries are extracted by segmenting low resolution images, whereas smaller structures are obtained through high resolution images.

Methods Based on Skeletons

The purpose of these methods is to obtain a *skeleton* of the coronary tree: a structure of smaller dimensions than the original that preserves the topological properties and the general shape of the detected object. Skeletons based on curves are generally used to reconstruct vascular structures (Nyström, Sanniti di Baja & Svensson, 2001). Skeletonizing algorithms are also called “thinning algorithms”.

The first step of the process is to detect the central axis of the vessels or “centerline”. This axis is an imaginary line that follows each vessel in its central axis, i.e. two normal segments that cross the axis in opposite sense should present the same distance from the vessel’s edges. The total of these lines constitutes the skeleton of the coronary tree. The methods that are used to detect the central axes can be classified into three categories:

Methods Based on Crests

One of the first methods to segment angiographic images on the basis of crests was proposed by Guo and

Richardson (Guo & Richardson, 1998). This method treats **angiographies** as topographic maps in which the detected crests constitute the central axes of the vessels.

The image is preprocessed by means of a median filter and smoothened with non-linear diffusion. The region of interest is then selected through **thresholding**, a process that eliminates the crests that do not correspond with the central axes. Finally, the candidate central axes are joined with curve relaxation techniques.

Methods Based on Regions Growth

Taking a known point as seed point, these techniques segment images through the incremental inclusion of pixels in a region on the basis of an *a priori* established criterion. There are two especially important criteria: similitude in the value, and spatial proximity (Jain, Kasturi & Schunck, 1995). It is established that pixels that are sufficiently near others with similar grey levels belong to the same object. The main disadvantage of this method is that it requires the intervention of the user to determine the seed points.

O’Brien and Ezquerro (O’Brien & Ezquerro, 1994) propose the automatic extraction of the coronary vessels in angiograms on the basis of temporary, spatial, and structural restrictions. The algorithm starts with a low-pass filter and the user’s definition of a seed point. The system then starts to extract the central axes by means of the “globe test” mechanism, after which the detected regions are entangled through the graph theory. The applied test also allows us to discard the regions that are detected incorrectly and do not belong to the vascular tree.

Methods Based on Differential Geometry

The methods that are based on differential geometry treat images as hypersurfaces and extract their features using curvature and surface crests. The points of hypersurface's crest correspond to the central axis of the structure of a vessel. This method can be applied to bidimensional as well as tridimensional images; angiograms are bidimensional images and are therefore modelled as tridimensional hypersurfaces.

Examples of reconstructions can be found in Prinnet et al (Prinnet, Mona & Rocchisani, 1995), who treat the images as parametric surfaces and extract their features by means of surfaces and crests.

Correspondence Filters Methods

The correspondence filter approach convolutes the image with multiple correspondence filters so as to extract the regions of interest. The filters are designed to detect different sizes and orientations.

Poli and Valli (Poli, R & Valli, 1997) apply this technique with an algorithm that details a series of multiorientation linear filters that are obtained as linear combinations of Gaussian "kernels". These filters are sensitive to different vessel widths and orientations.

Mao et al (Mao, Ruan, Bruno, Toumoulin, Collorec & Haigron, 1992) also use this type of filters in an algorithm based on visual perception models that affirm that the relevant parts of the objects in images with noise appear normally grouped.

Morphological Mathematical Methods

Mathematical morphology defines a series of operators that apply structural elements to the images so that

their morphological features can be preserved and irrelevant elements eliminated. The main morphological operations are the following:

- **Dilatation:** Expands objects, fills up empty spaces, and connects disjunct regions.
- **Erosion:** Contracts objects, separates regions.
- **Closure:** Dilatation + Erosion.
- **Opening:** Erosion + Dilatation.
- **"Top hat" transformation:** Extracts the structures with a linear shape
- **"Watershed" transformation:** "Inundates" the image that is taken as a topographic map, and extracts the parts that are not "flooded".

Eiho and Qian (Eiho & Qian, 1997) use a purely morphological approach to define an algorithm that consists of the following steps:

1. Application of the "top hat" operator to emphasize the vessels
2. Erosion to eliminate the areas that do not correspond to vessels
3. Extraction of the tree from a point provided by the user and on the basis of grey levels.
4. Slimming down of the tree
5. Extraction of edges through "watershed" transformation

MODEL-BASED TECHNIQUES

These approaches use explicit vessel models to extract the vascular tree. They can be divided into four categories:

Figure 2. Morphological operators applied to an angiography

ries: deformable models, parametric models, template correspondence models, and generalized cylinders.

Deformable Models

Strategies based on deformable models can be classified in terms of the work by McInerney and Terzopoulos (McInerney & Terzopoulos, 1997).

Algorithms that use deformable models (Merle, Finet, Lienard, & Magnin, 1997) are based on the progressive refining of an initial skeleton built with curves from a series of reference points:

- **Root points:** Starting points for the coronary tree.
- **Bifurcation points:** Points where a main branch divides into a secondary branch.
- **End points:** Points where a tree branch ends.

These points have to be marked manually.

Deformable Parametric Models: Active Contours

These models use a set of parametric curves that adjust to the object's edges and are modified by both external forces, that foment deformation, and internal forces that resist change. The active contour models or "snakes" in particular are a special case of a more general technique that pretends to adjust deformable models by minimizing energy.

Klein et al. (Klein, Lee & Amini, 1997) propose an algorithm that uses "snakes" for 4D reconstruction: they trace the position of each point of the central axis of a skeleton in a sequence of angiograms.

Deformable Geometric Models

These models are based on topographic models that are adapted for shape recognition. Malladi et al. (Malladi, Sethian & Vemuri, 1995) for instance adapt the "Level Set Method" (LSM) by representing an edge as a level zero set of a hypersurface of a superior order; the model evolves to reduce a metric defined by the restrictions of edges and curvature, but less rigidly than in the case of the "snakes". This edge, which constitutes the zero level of the hypersurface, evolves by adjusting to the edges of the vessels, which is what we want to detect.

Propagation Methods

Quek and Kirbas (Quek & Kirbas, 2001) developed a system of wave propagation combined with a back-tracking mechanism to extract the vessels from angiographic images. This method basically labels each pixel according to its likeliness to belong to a vessel and then propagates a wave through the pixels that are labeled as belonging to the vessel; it is this wave that definitively extracts the vessels according to the local features it encounters.

Approaches based on the correspondence of deformable templates:

This approach tries to recognize structural models (templates) in an image by using a template as context, i.e. as *a priori* model. This template is generally represented as a set of nodes connected by a segment. The initial structure is deformed until it adjusts optimally to the structures that were observed in the image.

Petrocelli et al. (Petrocelli, Manbeck, & Elion, 1993) describe a method based on deformable templates that also incorporates additional previous knowledge into the deformation process.

Parametric Models

These models are based on the *a priori* knowledge of the **artery's** shape and are used to build models whose parameters depend on the profiles of the entire vessel; as such, they consider the global information of the **artery** instead of merely the local information. The value of these parameters is established after a learning process.

The literature shows the use of models with circular sections (Shmueli, Brody, & Macovski, 1983) and spiral sections (Pappas, & Lim, 1984), because various studies by Brown, B. G., (Bolson, Frimer, & Dodge, 1977) (Brown, Bolson, Frimer & Dodge, 1982) show that sections of healthy arteries tend to be circular and sections with **stenosis** are usually elliptical. However, both circular and elliptical shapes fail to approach irregular shapes caused by pathologies or bifurcations.

This model has been applied to the reconstruction of vascular structures with two angiograms (Pellet, Herment, Sigelle, Horain, Maitre & Peronneau, 1994), which is why both healthy and stenotic sections are modeled by means of ellipses. This model is subsequently deformed until it corresponds to the shape associated to the birth of a new branch or pathology.

Figure 3. “Snakes” applied to a blood vessel. <http://vislab.cs.vt.edu/review/extraction.html>

Generalized Cylinder Models

A generalized cylinder (GC) is a solid whose central axis is a 3D curve. Each point of that axis has a limited and closed section that is perpendicular to it. A CG is therefore defined in space by a spatial curve or axis and a function that defines the section in that axis. The section is usually an ellipse. Technically, GCs should be included in the parametric methods section, but the work that has been done in this field is so extensive that it deserves its own category.

The construction of the coronary tree model requires one single view to build the 2D tree and estimate the sections. However, there is no information on the depth or the area of the sections, so a second projection will be required.

ARTERIAL TRACKING

Contrary to the approaches based on pattern recognition, where local operators are applied to the entire image, techniques based on arterial follow-up are based on the application of local operators in an area that presumably belongs to a vessel and that cover its length. From a given point of departure the operators detect the central axis and, by analyzing the pixels that are orthogonal to the tracking direction, the vessel's edges. There are various methods to determine the central axis and the edges: some methods carry out a sequential tracking and incorporate connectivity information after a simple edge detection operation, other methods use this information to sequentially track the contours. There are also approaches based on the intensity of the crests, on fuzzy sets, or on the representation of

Figure 4. Tracking applied to an angiography

A

graphs, where the purpose lies in finding the optimal road in the graph that represents the image.

Lu and Eiho (Lu, Eiho, 1993) have described a follow-up algorithm for the vascular edges in **angiographies** that considers the inclusion of branches and consists of three steps:

1. Edge detection
2. Branch search
3. Tracking of sequential contours

The user must provide the point of departure, the direction, and the search range. The edge points are evaluated with a differential smoothening operator in a line that is perpendicular to the direction of the vessel. This operator also serves to detect the branches.

TECHNIQUES BASED ON ARTIFICIAL INTELLIGENCE

Approaches based on Artificial Intelligence use high-level knowledge to guide the **segmentation** and delineation of vascular structures and sometimes use different types of knowledge from various sources.

One possibility (Smets, Verbeeck, Suetens, & Oosterlinck, 1988) is to use rules that codify knowledge on the morphology of blood vessels; these rules

are then used to formulate a hierarchy with which to create the model. This type of system does not offer any good results in arterial bifurcations or in arteries with occlusions.

Another approach (Stansfield, 1986) consists in formulating a rules-based **Expert System** to identify the arteries. During the first phase, the image is processed without making use of domain knowledge to extract segments of the vessels. It is only in the second phase that domain knowledge on cardiac anatomy and physiology is applied.

The latter approach is more robust than the former; but it presents the inconvenience of not combining all the segments into one vascular structure.

FUTURE TRENDS

It cannot be said that one technique has a more promising future than another, but the current tendency is to move away from the abovementioned classical **segmentation** algorithms towards 3D and even 4D reconstructions of the coronary tree.

Other lines of research focus on obtaining angiograph images by means of new acquisition technologies such as Magnetic Resonance, **Computerized High Speed Tomography**, or two-armed angiograph devices that achieve two simultaneous projections in

combination with the use of ultrasound intravascular devices. This type of acquisition simplifies the creation of tridimensional structures, either directly from the acquisition or after a simple processing of the bidimensional images.

KEY TERMS

Angiography: Image of blood vessels obtained by any possible procedure.

Artery: Each of the vessels that take the blood from the heart to the other bodyparts.

Computerized Tomography: Exploration of X-rays that produces detailed images of axial cuts of the

body. A CT obtains many images by rotating around the body. A computer combines all these images into a final image that represents the bodycut like a slice.

Expert System: Computer or computer program that can give responses that are similar to those of an expert.

Segmentation: In computer vision, segmentation refers to the process of partitioning a digital image into multiple regions. The goal of segmentation is to simplify and/or change the representation of an image into something that is more meaningful and easier to analyze. Image segmentation is typically used to locate objects and boundaries (structures) in images, in this case, the coronary tree in digital angiography frames.

Stenosis: A stenosis is an abnormal narrowing in a blood vessel or other tubular organ or structure. A coronary artery that's constricted or narrowed is called stenosed. Buildup of fat, cholesterol and other substances over time may clog the artery. Many heart attacks are caused by a complete blockage of a vessel in the heart, called a coronary artery.

Thresholding: A technique for the processing of digital images that consists in applying a certain property or operation to those pixels whose intensity value exceeds a defined threshold.

ANN Application in the Field of Structural Concrete

Juan L. Pérez

Manuel F. Herrador

University of A Coruña, Spain

INTRODUCTION

Artificial Intelligence (AI) mechanisms are more and more frequently applied to all sorts of civil engineering problems. New methods and algorithms which allow civil engineers to use these techniques in a different way on diverse problems are available or being made available. One AI techniques stands out over the rest: Artificial Neural Networks (ANN). Their most remarkable traits are their ability to learn, the possibility of generalization and their tolerance towards mistakes. These characteristics make their use viable and cost-efficient in any field in general, and in Structural Engineering in particular. The most extended construction material nowadays is concrete, mainly because of its high resistance and its adaptability to formwork during its fabrication process. Along this chapter we will find different applications of ANNs to structural concrete.

Artificial Neural Networks

Warren McCulloch and Walter Pitts are credited for the origin of Artificial Networks in the 1940s, since they were the first to design an artificial neuron (McCulloch & Pitts, 1943). They proposed the binary mode (active or inactive) neuron model with a fixed threshold which must be surpassed for it to change state. Some of the concepts they introduced still hold useful today.

Artificial Neural Networks intend to simulate the properties found in biological neural systems through mathematical models by the way of artificial mechanisms. A neuron is considered a formal element, or module, or basic network unit which receives

information from other modules or the environment; it then integrates and computes this information to emit a single output which will be identically transmitted to subsequent multiple neurons (Wasserman, 1989).

The output of an artificial neuron is determined by its propagation or excitation, activation and transfer functions.

The propagation function is generally the summation of each input multiplied by the weight of its interconnection (net value):

$$n_i = \sum_{j=0}^{N-1} [w_{ij} \cdot p_j] \quad (1)$$

The activation function modifies the latter, relating the neural input to the next activation state.

$$a_i(t) = FA[a_i(t-1), n_i(t-1)] \quad (2)$$

The transfer function is applied to the result of the activation function. It is used to bound the neuron's output and is generally given by the interpretation intended for the output. Some of the most commonly used transfer functions are the sigmoid (to obtain values in the [0,1] interval) and the hyperbolic tangent (to obtain values in the [-1,1] interval).

$$out_i = FT(a_i(t)) \quad (3)$$

Once each element in the process is defined, the type of network (network topology) to use must be designed. These can be divided in forward-feed networks, where

information moves in one direction only (from input to output), and networks with partial or total feedback, where information can flow in any direction.

Finally, learning rules and training type must be defined. Learning rules are divided in supervised and non-supervised (Brown & Harris, 1994) (Lin & Lee, 1996) and within the latter, self-organizing learning and reinforcement learning (Hoskins & Himmelblau, 1992). The type of training will be determined by the type of learning chosen.

An Introduction to Concrete (Material and Structure)

Structural concrete is a construction material created from the mixture of cement, water, aggregates and additions or admixtures with diverse functions. The goal is to create a material with rock-like appearance, with sufficient compressive strength and the ability to adopt adequate structural shapes. Concrete is moldable during its preparation phase, once the components have mixed together go produce a fluid mass which conveniently occupies the cavities in a mould named formwork. After a few hours, concrete hardens thanks to the chemical hydration reaction experimented by cement, generating a paste which envelops the aggregates and gives the ensemble the appearance of an artificial rock somewhat similar to a conglomerate.

Hardened concrete offers good compressive strength, but very low tensile strength. This is why structures created with this material must be reinforced by use of steel rebars, configured by rods which are placed (before pouring the concrete) along the lines where calculation predicts the highest tensile stresses. Cracking, which reduces the durability of the structure, is thus hindered, and sufficient resistance is guaranteed with a very low probability of failure. The entirety formed by concrete and rebar is referred to as Structural Concrete (Shah, 1993).

Two phases thus characterize the evolution of concrete in time. In the first phase, concrete must be fluid enough to ensure ease of placement, and a time to initial set long enough to allow transportation from plant to worksite. Flowability depends basically on the type and quantity of the ingredients in the mixture. Special chemical admixtures (such as plasticizers and superplasticizers) guarantee flowability without grossly increasing the amount of water, whose ratio relative to the amount of cement (or water/cement ratio, w/c) is on

reverse proportion to strength attained. The science of rheology deals with the study of the behavior of fresh concrete. A variety of tests can be used to determine flowability of fresh concrete, the most popular amongst them being the Abrams cone (Abrams, 1922) or slump cone test (Domone, 1998).

The second phase (and longest over time) is the hardened phase of concrete, which determines the behavior of the structure it gives shape to, from the point of view of serviceability (by imposing limitations on cracking and compliance) and resistance to failure (by imposing limitations on the minimal loads that can be resisted, as compared to the internal forces produced by external loading), always within the frame of sufficient durability for the service life foreseen.

The study of structural concrete from every point of view has been undertaken following many different optics. The experimental path has been very productive, generating along the past 50 years a database (with a tendency to scatter) which has been used to sanction studies carried along the second and third path that follow. The analytical path also constitutes a fundamental tool to approach concrete behavior, both from the material and structural point of view. Development of theoretical behavior models goes back to the early 20th century, and theoretical equations developed since have been corrected through testing (as mentioned above) before becoming a part of codes and specifications. This method of analysis has been reinforced with the development of numerical methods and computational systems, capable of solving a great number of simultaneous equations. In particular, the Finite Element Method (and other methods in the same family) and optimization techniques have brought a remarkable capacity to approximate behavior of structural concrete, having their results benchmarked in many applications by the aforementioned experimental testing.

Three basic lines of study are thus available. Being complementary between them, they have played a decisive role in the production of national and international codes and rules which guide or legislate the project, execution and maintenance of structural concrete works. Concrete is a complex material, which presents a number of problems for analytical study, and so is an adequate field for the development of analysis techniques based on neural networks (Gonzalez, Martínez and Carro, 2006)

Application of Artificial Neural Networks to problems in the field of structural concrete has unfolded in the past few years in two ways. On one hand, analytical and structural optimization systems faster than traditional (usually iterative) methods have been generated starting with expressions and calculation rules. On the other, the numerous databases created from the large amount of tests published in the scientific community have allowed for the development of very powerful ANN which have thrown light on various complex phenomena. In a few cases, specific designed codes have been improved through the use of these techniques; some examples follow.

Application of Artificial Neural Networks to Optimization Problems

Design of concrete structures is based on the determination of two basic parameters: member thickness (effective depth d , depth of a beam or slab section measured from the compression face to the centroid of reinforcement) and amount of reinforcement (established as the total area A_s of steel in a section, materialized as rebars, or the reinforcement ratio, the ratio between steel area and concrete area in the section). Calculation methods are iterative, since a large number of conditions must be verified in the structure, and the aforementioned parameters are fixed as a function of three basic conditions which are sequentially followed: structural safety, maximum ductility at failure and minimal cost. Design rules, expressed through equations, allow for a first solution which is corrected to meet all calculation scenarios, finally converging when the difference between input and output parameters are negligible.

In some cases it is possible to develop optimization algorithms, whose analytical formulation opens the way to the generation of a database. Hadi (Hadi, 2003) has performed this work for simply supported reinforced concrete beams, and the expressions obtained after the optimization process determine the parameters specified above, while simultaneously assigning the cost associated to the optimal solution (related to the cost of materials and formwork). With these expressions, Hadi develops a database with the following variables: applied flexural moment (M), compressive strength of concrete (f_c), steel strength (f_y), section width (b), section depth (h), and unit costs of concrete (C_c), steel (C_s) and formwork (C_f).

Network parameters used are as follows. The number of training samples is 550; number of input layer neurons is 8; number of hidden layer neurons is 10; number of output layer neurons is 4; type of backpropagation is Levenberg–Marquardt backpropagation; activation function is sigmoidal function; learning rate; 0.01; number of epochs is 3000; sum-square error achieved is 0.08. The network had been tested with 50 samples and yielded the average error of 6.1%.

Hadi studies various factors when choosing network architecture and backpropagation algorithm type. When two layers of hidden neurons are used, precision is not improved while computation time is increased. The number of samples depends on the complexity of the problem and the number of input and output parameters. If a value is fixed for the input costs, there are no noticeable precision improvements between training the network with 200 or 1000 samples. When costs are introduced as input parameters, 100 samples are not enough to achieve convergence in training. Finally, the training algorithm is also checked, studying the range between pure backpropagation (too slow for training), backpropagation with momentum and with adaptive learning, backpropagation with Levenberg–Marquardt updating rule and fast learning backpropagation. The latter is finally retained since it requires less time to get the network to converge while providing very good results (Demuth, H. & Beale, M., 1995)

Application of Artificial Neural Networks to Prediction of Concrete Physical Parameters Measurable Through Testing: Concrete Strength and Consistency

Other neural network applications are supported by large experimental databases, created through years of research, which allow for the prediction of phenomena with complex analytical formulation.

One of these cases is the determination of two basic concrete parameters: its workability when mixed, necessary for ease of placement in concrete, and its compressive strength once hardened, which is basic to the evaluation of the capacity of the structure. The variables that necessarily determine these two parameters are the components of concrete: amounts of cement, water, fine aggregate (sand), coarse aggregate (small gravel and large gravel), and other components such as pozzolanic additions (which bring soundness

and delayed strength increase, especially in the case of fly ash and silica fume) and admixtures (which fluidify the fresh mixture allowing the use of reduced amounts of water). There are still no analytical or numerical models that faithfully predict fresh concrete consistency (related to flowability, and usually evaluated by the slump of a molded concrete cone) or compressive strength (determined by crushing of prismatic specimens in a press).

Öztaş et al. (Öztaş, Pala, Özbay, Kanca, Çağlar & Batı, 2006) have developed a neural network from 187 concrete mixes, for which all parameters are known, using 169 of them for training and 18, randomly selected, for verification. Database variables are sometimes taken as a ratio between them, since there is available knowledge about the dependency of slump and strength on such parameters. The established range for the 7 parameter set is shown in Table 1.

Network architecture, as determined by 7 input neurons and two hidden layers of 5 and 3 neurons respectively.

The back-propagation learning algorithm has been used in feed-forward two hidden-layers. The learning algorithm used in the study is scaled conjugate gradients algorithm (SCGA), activation function is sigmoidal function, and number of epochs is 10,000. The prediction capacity of the network is better in the “Compressive Strength” output (maximum error of 6%) than in the

“Slump” output (errors up to 25%). This is due to the fact that the relation between the chosen variables and strength is much stronger than in the case of slump, which is influenced by other non-contemplated variables (e. g. type and power of concrete mixer, mixing order of components, aggregate moisture) and the method for measurement of consistency, whose adequacy for the particular type of concrete used in the database is questioned by some authors.

Application of Artificial Neural Networks to the Development of Design Formulae and Codes

The last application presented in this paper is the response analysis to shear forces in concrete beams. These forces generate transverse tensile stresses in concrete beams which require placement of rebars perpendicular to the beam axis, known as hoops or ties. Analytical determination of failure load from the variables that intervene in this problem is very complex, and in general most of the formulae used today are based on experimental interpolations with no dimensional consistency. Cladera and Marí (Cladera & Marí, 2004) have studied the problem through laboratory testing, developing a neural network for the strength analysis of beams with no shear reinforcement. They rely on a database compiled by Bentz (Bentz, 2000) and Kuchma (Kuchma, 2002), where the variables are effective depth (d), beam width (b , though introduced as d/b), shear span (a/d , see Figure 1), longitudinal reinforcement ratio ($\rho_l = A_s/bd$) and compressive strength of concrete (f_c). Of course, failure load is provided for each of the 177 tests found in the database. They use 147 tests to train the network and 30 for verification, on a one layer architecture with 10 hidden neurons and a retropropagation learning mechanism. The ranges

Table 1. Input parameter range

| Input parameters | Minimum | Maximum |
|--------------------------------------|---------|---------|
| W/B (ratio, %) ^a | 18 | 45 |
| W (kg/m ³) ^b | 140 | 165 |
| s/a (ratio, %) ^c | 35 | 52 |
| FA (ratio, %) ^d | 0 | 20 |
| AE (kg/m ³) ^e | 0.036 | 0.078 |
| SF (ratio, %) ^f | 5 | 25 |
| SP (kg/m ³) ^g | 1.89 | 36.5 |

(a) [Water]/[binder] ratio, considering binder as the lump sum of cement, fly ash and silica fume

(b) Amount of water

(c) [Amount of sand]/[Total aggregate (sand+small gravel+large gravel)]

(d) Percentage of cement substituted by fly ash

(e) Amount of air-entraining agent

(f) Percentage of cement substituted by silica fume

(g) Amount of superplasticizer

Table 2 Input parameter ranges

| Parameter | Minimum | Maximum |
|-----------------|---------|---------|
| d (mm) | 101.6 | 1090 |
| d/b | 0.37 | 7.17 |
| ρ_l (%) | 0.50 | 6.64 |
| f_c (MPa) | 14.7 | 101.8 |
| a/d | 2.48 | 7.86 |
| V_{fail} (kN) | 19.52 | 332.14 |

Figure 1. Span loading a of a beam. (González, 2002)

Table 3. Comparison between available codes and proposed equations for shear strength.

| Procedure | ACI 11-5 | ACI 11-3 | MC-90 | EC-2 | AASHTO | Eq.(7) | Eq.(8) |
|--------------------|----------|----------|-------|-------|--------|--------|--------|
| Average | 1.16 | 1.29 | 1.15 | 1.02 | 1.28 | 1.15 | 1.13 |
| Median | 1.15 | 1.25 | 1.16 | 0.99 | 1.25 | 1.14 | 1.12 |
| Standard deviation | 0.31 | 0.40 | 0.19 | 0.23 | 0.22 | 0.18 | 0.19 |
| CoV (%) | 26.89 | 31.21 | 16.57 | 22.03 | 16.80 | 15.73 | 16.42 |
| Minimum | 0.42 | 0.42 | 0.65 | 0.57 | 0.86 | 0.73 | 0.78 |
| Maximum | 2.14 | 2.47 | 1.78 | 1.78 | 2.14 | 1.69 | 1.85 |

for the variables are shown on Table 2. Almost 8000 iterations were required to attain best results.

The adjustment provided by training presents an average ratio V_{test}/V_{pred} of 0.99, and 1.02 in validation. The authors have effectively created a laboratory with a neural network, in which they “test” (within parameter range) new beams by changing exclusively one parameter each time. Finally, they come up with two alternative design formulae that improve noticeably any given formula developed up to that moment. Table 3 presents a comparison between those two expressions (named Eq. 7 and Eq. 8) and others found in a series of international codes.

CONCLUSION

- The field of structural concrete shows great potential for the application of neural networks. Successful approaches to optimization, prediction of complex physical parameters and design formulae development have been presented.
- The network topology used in most cases for structural concrete is forward-feed, multilayer with backpropagation, typically with one or two hidden

layers. The most commonly used training algorithms are descent gradient with momentum and adaptive learning, and Levenberg-Marquardt.

- The biggest potential of ANNs is their capacity to generate virtual testing laboratories which substitute with precision expensive real laboratory tests within the proper range of values. A methodical “testing” program throws light on the influence of the different variables in complex phenomena at reduced cost.
- The field of structural concrete counts upon extensive databases, generated through the years, that can be analyzed with this technique. An effort should be made to compile and homogenize these databases to extract the maximum possible knowledge, which has great influence on structural safety.

KEY TERMS

Compression: Stress generated by pressing or squeezing.

Consistency: The relative mobility or ability of freshly mixed concrete or mortar to flow; the usual measurement for concrete is *slump*, equal to the subsidence measured to the nearest 1/4 in. (6 mm) of a molded specimen immediately after removal of the slump cone.

Ductility: That property of a material by virtue of which it may undergo large permanent deformation without rupture.

Formwork: Total system of support for freshly placed concrete including the mold or sheathing that contacts the concrete as well as supporting members, hardware, and necessary bracing; sometimes called *shuttering* in the UK.

Shear Span: Distance between a reaction and the nearest load point.

Structural Safety: Structural response stronger than the internal forces produced by external loading.

Tension: Stress generated by stretching.

ANN Development with EC Tools: An Overview

Daniel Rivero

Juan Rabuñal

University of A Coruña, Spain

INTRODUCTION

Among all of the Artificial Intelligence techniques, Artificial Neural Networks (ANNs) have shown to be a very powerful tool (McCulloch & Pitts, 1943) (Haykin, 1999). This technique is very versatile and therefore has been successfully applied to many different disciplines (classification, clustering, regression, modellization, etc.) (Rabuñal & Dorado, 2005).

However, one of the greatest problems when using ANNs is the great manual effort that has to be done in their development. A big myth of ANNs is that they are easy to work with and their development is almost automatically done. This development process can be divided into two parts: architecture development and training and validation. As the network architecture is problem-dependant, the design process of this architecture used to be manually performed, meaning that the expert had to test different architectures and train them until finding the one that achieved best results after the training process. The manual nature of the described process determines its slow performance although the training part is completely automated due to the existence of several algorithms that perform this part.

With the creation of Evolutionary Computation (EC) tools, researchers have worked on the application of these techniques to the development of algorithms for automatically creating and training ANNs so the whole process (or, at least, a great part of it) can be automatically performed by computers and therefore few human efforts has to be done in this process.

BACKGROUND

EC is a set of tools based on the imitation of the natural behaviour of the living beings for solving optimization problems. One of the most typical subset of tools inside

EC is called Evolutionary Algorithms (EAs), which are based on natural evolution and its implementation on computers. All of these tools work with the same basis: a population of solutions to that particular problem is randomly created and an evolutionary process is applied to it. From this initial random population, the evolution is done by means of selection and combination of the best individuals (although the worst ones also have a small probability of being chosen) to create new solutions. This process is carried out by selection, crossover, and mutation operators. These operators are typically used in biology in its evolution for adaptation and survival. After several generations, it is hoped that the population contains a good solution to the problem.

The first EA to appear was Genetic Algorithms (GAs), in 1975 (Holland, 1975). With the working explained above, GAs use a binary codification (i.e., each solution is codified into a string of bits). Later, in the early 90s a new technique appeared, called Genetic Programming (GP). This one is based on the evolution of trees, i.e., each individual is codified as a tree instead of a binary string. This allows its application to a wider set of environments.

Although GAs and GP are the two most used techniques in EAs, more tools can be classified as part of this world, such as Evolutionary Programming or Evolution Strategies, all of them with the same basis: the evolution of a population following the natural evolution rules.

DEVELOPMENT OF ANNS WITH EC TOOLS

The development of ANNs is a topic that has been extensively dealt with very diverse techniques. The world of evolutionary algorithms is not an exception, and proof of that is the great amount of works that have

been published about different techniques in this area (Cantú-Paz & Kamath, 2005). These techniques follow the general strategy of an evolutionary algorithm: an initial population consisting of different genotypes, each one of them codifying different parameters (typically, the weight of the connections and / or the architecture of the network and / or the learning rules), and is randomly created. This population is evaluated in order to determine the fitness of each individual. Afterwards, this population is repeatedly made to evolve by means of different genetic operators (replication, crossover, mutation, etc.) until a determined termination criteria is fulfilled (for example, a sufficiently good individual is obtained, or a predetermined maximum number of generations is achieved).

Essentially, the ANN generation process by means of evolutionary algorithms is divided into three main groups: evolution of the weights, architectures, and learning rules.

Evolution of Weights

The evolution of the weights begins with a network with a predetermined topology. In this case, the problem is to establish, by means of training, the values of the network connection weights. This is generally conceived as a problem of minimization of the network error, taken, for example, as the result of the Mean Square Error of the network between the desired outputs and the ones achieved by the network. Most the training algorithms, such as the backpropagation algorithm (BP) (Rumelhart, Hinton & Williams, 1986), are based on gradient minimization. This has several drawbacks (Whitley, Starkweather & Bogart, 1990), the most important is that quite frequently the algorithm becomes stuck in a local minimum of the error function and is unable of finding the global minimum, especially if the error function is multimodal and / or non-differentiable. One way of overcoming these problems is to carry out the training by means of an Evolutionary Algorithm (Whitley, Starkweather & Bogart, 1990); i.e., formulate the training process as the evolution of the weights in an environment defined by the network architecture and the task to be done (the problem to be solved). In these cases, the weights can be represented in the individuals' genetic material as a string of binary values (Whitley, Starkweather & Bogart, 1990) or a string of real numbers (Greenwood, 1997). Traditional genetic algorithms (Holland, 1975) use a genotypic codification

method with the shape of binary strings. In this way, much work has emerged that codifies the values of the weights by means of a concatenation of the binary values which represent them (Whitley, Starkweather & Bogart, 1990). The big advantage of these approximations is their generality and that they are very simple to apply, i.e., it is very easy and quick to apply the operators of uniform crossover and mutation on a binary string. The disadvantage of using this type of codification is the problem of permutation. This problem was raised upon considering that the order in which the weights are taken in the string causes equivalent networks to possibly correspond with totally different individuals. This leads the crossing operator to become very inefficient. Logically, the weight value codification has also emerged in the form of real number concatenation, each one of them associated with a determined weight (Greenwood 1997). By means of genetic operators designed to work with this type of codification, and given that the existing ones for bit string cannot be used here, several studies (Montana & Davis, 1989) showed that this type of codification produces better results and with more efficiency and scalability than the BP algorithm.

Evolution of the Architectures

The evolution of the architectures includes the generation of the topological structure; i.e., the topology and connectivity of the neurons, and the transfer function of each neuron of the network. The architecture of a network has a great importance in order to successfully apply the ANNs, as the architecture has a very significant impact on the process capacity of the network. In this way, on one hand, a network with few connections and a lineal transfer function may not be able to resolve a problem that another network having other characteristics (distinct number of neurons, connections or types of functions) would be able to resolve. On the other hand, a network having a high number of non-linear connections and nodes could be overfitted and learn the noise which is present in the training as an inherent part of it, without being able to discriminate between them, and in the end, not have a good generalization capacity. Therefore, the design of a network is crucial, and this task is classically carried out by human experts using their own experience, based on "trial and error", experimenting with a different set of architectures. The evolution of architectures has

been possible thanks to the appearance of constructive and destructive algorithms (Sietsma & Dow, 1991). In general terms, a constructive algorithm begins with a minimum network (with a small number of layers, neurons and connections) and successively adds new layers, nodes and connections, if they are necessary, during the training. A destructive algorithm carries out the opposite operation, i.e., it begins with a maximum network and eliminates unnecessary nodes and connections during the training. However, the methods based on Hill Climbing algorithms are quite susceptible into falling to a local minimum (Angeline, Suders & Pollack, 1994).

In order to develop ANN architectures by means of an evolutionary algorithm, it is necessary to decide how to codify a network inside the genotype so it can be used by the genetic operators. For this, different types of network codifications have emerged.

In the first codification method, direct codification, there is a one-to-one correspondence between the genes and the phenotypic representation (Miller, Todd & Hedge, 1989). The most typical codification method consists of a matrix $C=(c_{ij})$ of $N \times N$ size which represents an architecture of N nodes, where c_{ij} indicates the presence or absence of a connection between the i and j nodes. It is possible to use $c_{ij}=1$ to indicate a connection and $c_{ij}=0$ to indicate an absence of connection. In fact, c_{ij} could take real values instead of Booleans to represent the value of the connection weight between neuron “ i ” and “ j ”, and in this way, architecture and connections can be developed simultaneously (Alba, Aldana & Troya, 1993). The restrictions which are required in the architectures can easily be incorporated into this representational scheme. For example, a feed-forward network would have non-zero coefficients only in the upper right hand triangle of the matrix. These types of codification are generally very simple and easy to implement. However, they have a lot of disadvantages, such as scalability, the impossibility of codifying repeated structures, or permutation (i.e., different networks which are functionally equivalent can correspond with different genotypes) (Yao & Liu, 1998).

As a counterproposal to this type of direct codification method, there are also the indirect codification types in existence. With the objective of reducing the length of the genotypes, only some of the characteristics of the architecture are codified into the chromosome. Within this type of codification, there are various types of representation.

First, the parametric representations have to be mentioned. The network can be represented by a set of parameters such as the number of hidden layers, the number of connections between two layers, etc. There are several ways of codifying these parameters inside the chromosome (Harp, Samad & Guha, 1989). Although the parametric representations can reduce the length of the chromosome, the evolutionary algorithm makes a search in a limited space within the possible searchable space that represents all the possible architectures. Another type of non-direct codification is based on a representational system with the shape of grammatical rules (Yao & Shi, 1995). In this system, the network is represented by a set of rules, with shape of production rules, which will build a matrix that represents the network.

Other types of codification, more inspired in the world of biology, are the ones known as “growing methods”. With them, the genotype does not codify the network any longer, but instead it contains a set of instructions. The decodification of the genotype consists of the execution of these instructions, which will provoke the construction of the phenotype (Husbands, Harvey, Cliff & Miller, 1994). These instructions usually include neural migrations, neuronal duplication or transformation, and neuronal differentiation.

Finally, and within the indirect codification methods, there are other methods which are very different from the ones already described. Andersen describes a technique in which each individual of a population represents a hidden node instead of the architecture (Andersen & Tsoi, 1993). Each hidden layer is constructed automatically by means of an evolutionary process which uses a genetic algorithm. This method has the limitation that only feed-forward networks can be constructed and there is also a tendency for various nodes with a similar functionality to emerge, which inserts some redundancy inside the network that must be eliminated.

One important characteristic is that, in general, these methods only develop architectures, which is the most common, or else architectures and weights together. The transfer function of each architecture node is assumed to have been previously determined by a human expert, and that it is the same for all of the network nodes (at least, for all of the nodes of the same layer), although the transfer function has been shown to have a great importance on the behaviour of the network (Lovell & Tsoi, 1992). Few methods have

been developed which cause the transfer function to evolve, and, therefore, had little repercussion in the world of ANNs with EC.

Evolution of the Learning Rule

Another interesting approximation to the development of ANNs by means of EC is the evolution of the learning rule. This idea emerges because a training algorithm works differently when it is applied to networks with different architectures. In fact, and given that a priori, the expert usually has very few knowledge about a network, it is preferable to develop an automatic system to adapt the learning rule to the architecture and the problem to be resolved.

There are several approximations to the evolution of the learning rule (Crosher, 1993) (Turney, Whitley & Anderson, 1996), although most of them are based only on how the learning can modify or guide the evolution, and in the relation between the architecture and the connection weights. Actually, there are few works that focus on the evolution of the learning rule in itself (Bengio & Bengio, Cloutier & Gecsei, 1992) (Ribert, Stocker, Lecourtier & Ennaji, 1994).

One of the most common approaches is based on setting the parameters of the BP algorithm: learning rate and momentum. Some authors propose methods in which an evolutionary process is used to find these parameters while leaving the architecture constant (Kim, Jung, Kim & Park, 1996). Other authors, on the other hand, propose codifying these BP algorithm parameters together with the network architecture inside of the individuals of the population (Harp, Samad & Guha, 1989).

FUTURE TRENDS

The evolution of ANNs has been a research topic since some decades ago. The creation of new EC and, in general, new AI techniques and the evolution and improvement of the existing ones allow the development of new methods of automatically developing of ANNs. Although there are methods that (more or less) automatically develop ANNs, they are usually not very efficient, since evolution of architectures, weights and learning rules at once leads to having a very big search space, so this feature definitely has to be improved.

CONCLUSION

The world of EC has provided a set of tools that can be applied to optimization problems. In this case, the problem is to find an optimal architecture and/or weight value set and/or learning rule. Therefore, the development of ANNs was converted into an optimization problem. As the described techniques show, the use of EC techniques has made possible the development of ANNs without human intervention, or, at least, minimising the participation of the expert in this task.

As has been explained, these techniques have some problems. One of them is the already explained permutation problem. Another problem is the loss of efficiency: the more complicated the structure to evolve is (weights, learning rule, architecture), less efficient the system will be, because the search space becomes much bigger. If the system has to evolve several things at a time (for example, architecture and weights so the ANN development is completely automated), this loss of efficiency increases. However, these systems still work faster than the whole manual process of designing and training several times an ANN.

KEY TERMS

Artificial Neural Networks: Interconnected set of many simple processing units, commonly called neurons, that use a mathematical model, that represents an input/output relation,

Back-Propagation Algorithm: Supervised learning technique used by ANNs, that iteratively modifies the weights of the connections of the network so the error given by the network after the comparison of the outputs with the desired one decreases.

Evolutionary Computation: Set of Artificial Intelligence techniques used in optimization problems, which are inspired in biologic mechanisms such as natural evolution.

Genetic Programming: Machine learning technique that uses an evolutionary algorithm in order to optimise the population of computer programs according to a fitness function which determines the capability of a program for performing a given task.

Genotype: The representation of an individual on an entire collection of genes which the crossover and mutation operators are applied to.

Phenotype: Expression of the properties coded by the individual's genotype.

Population: Pool of individuals exhibiting equal or similar genome structures, which allows the application of genetic operators.

Search Space: Set of all possible situations of the problem that we want to solve could ever be in.

ANN-Based Defects' Diagnosis of Industrial Optical Devices

INTRODUCTION

A major step for high-quality optical devices faults diagnosis concerns scratches and digs defects detection and characterization in products. These kinds of aesthetic flaws, shaped during different manufacturing steps, could provoke harmful effects on optical devices' functional specificities, as well as on their optical performances by generating undesirable scatter light, which could seriously damage the expected optical features. A reliable diagnosis of these defects becomes therefore a crucial task to ensure products' nominal specification. Moreover, such diagnosis is strongly motivated by manufacturing process correction requirements in order to guarantee mass production quality with the aim of maintaining acceptable production yield.

Unfortunately, detecting and measuring such defects is still a challenging problem in production conditions and the few available automatic control solutions remain ineffective. That's why, in most of cases, the diagnosis is performed on the basis of a human expert based visual inspection of the whole production. However, this conventionally used solution suffers from several acute restrictions related to human operator's intrinsic limitations (reduced sensitivity for very small defects, detection exhaustiveness alteration due to attentiveness shrinkage, operator's tiredness and weariness due to repetitive nature of fault detection and fault diagnosis tasks).

To construct an effective automatic diagnosis system, we propose an approach based on four main

operations: defect detection, data extraction, dimensionality reduction and neural classification. The first operation is based on Nomarski microscopy issued imaging. These issued images contain several items which have to be detected and then classified in order to discriminate between "false" defects (correctable defects) and "abiding" (permanent) ones. Indeed, because of industrial environment, a number of correctable defects (like dusts or cleaning marks) are usually present beside the potential "abiding" defects. Relevant features extraction is a key issue to ensure accuracy of neural classification system; first because raw data (images) cannot be exploited and, moreover, because dealing with high dimensional data could affect learning performances of neural network. This article presents the automatic diagnosis system, describing the operations of the different phases. An implementation on real industrial optical devices is carried out and an experiment investigates a MLP artificial neural network based items classification.

BACKGROUND

Today, the only solution which exists to detect and classify optical surfaces' defects is a visual one, carried out by a human expert. The first originality of this work is in the sensor used: Normarski microscopy. Three main advantages distinguishing Normarski microscopy (known also as "Differential Interference Contrast microscopy" (Bouchareine, 1999) (Chatterjee, 2003))

from other microscopy techniques, have motivated our preference for this imaging technique. The first of them is related to the higher sensitivity of this technique comparing to the other classical microscopy techniques (Dark Field, Bright Field) (Flewitt & Wild, 1994). Furthermore, the DIC microscopy is robust regarding lighting non-homogeneity. Finally, this technology provides information relative to depth (3-th dimension) which could be exploited to typify roughness or defect's depth. This last advantage offers precious additional potentiality to characterize scratches and digs flaws in high-tech optical devices. Therefore, Nomarski microscopy seems to be a suitable technique to detect surface imperfections.

On the other hand, since they have shown many attractive features in complex pattern recognition and classification tasks (Zhang, 2000) (Egmont-Petersen, de Ridder, & Handels, 2002), artificial neural network based techniques are used to solve difficult problems. In our particular case, the problem is related to the classification of small defects on a great observation's surface. These promising techniques could however encounter difficulties when dealing with high dimensional data. That's why we are also interested in data dimensionality reducing methods.

DEFECTS' DETECTION AND CLASSIFICATION

The suggested diagnosis process is described in broad outline in the diagram of Figure 1. Every step is presented, first detection and data extraction phases and then classification phase coupled with dimensionality reduction. In a second part, some investigations on real industrial data are carried out and the obtained results are presented.

Detection and Data Extraction

The aim of defect's detection stage is to extract defects images from DIC detector issued digital image. The

proposed method (Voiry, Houbre, Amarger, & Madani, 2005) includes four phases:

- Pre-processing: DIC issued digital image transformation in order to reduce lighting heterogeneity influence and to enhance the aimed defects' visibility,
- Adaptive matching: adaptive process to match defects,
- Filtering and segmentation: noise removal and defects' outlines characterization.
- Defect image extraction: correct defect representation construction.

Finally, the image associated to a given detected gives an isolated (from other items) representation of the defect (e.g. depicts the defect in its immediate environment), like depicted in Figure 2.

But, information contained in such generated images is highly redundant and these images don't have necessarily the same dimension (typically this dimension can turn out to be hundred times as high). That is why this raw data (images) can not be directly processed and has first to be appropriately encoded, using some transformations. Such ones must naturally be invariant with regard to geometric transformations (translation, rotation and scaling) and robust regarding different perturbations (noise, luminance variation and background variation). Fourier-Mellin transformation is used as it provides invariant descriptors, which are considered to have good coding capacity in classification tasks (Choksuriwong, Laurent, & Emile, 2005) (Derrode, 1999) (Ghorbel, 1994). Finally, the processed features have to be normalized, using the centring-reducing transformation. Providing a set of 13 features using such transform, is a first acceptable compromise between industrial environment real-time processing constraints and defect image representation quality (Voiry, Madani, Amarger, & Houbre, 2006).

Figure 2. Images of characteristic items: (a) Scratch; (b) dig; (c) dust; (d) cleaning marks

Dimensionality Reduction

To obtain a correct description of defects, we must consider more or less important number of Fourier-Mellin invariants. But dealing with high-dimensional data poses problems, known as “curse of dimensionality” (Verleysen, 2001). First, sample number required to reach a predefined level of precision in approximation tasks increases exponentially with dimension. Thus, intuitively, the sample number needed to properly learn problem becomes quickly much too large to be collected by real systems, when dimension of data increases. Moreover surprising phenomena appear when working in high dimension (Demartines, 1994): for example, variance of distances between vectors remains fixed while its average increases with the space dimension, and Gaussian kernel local properties are also lost. These last points explain that behaviour of a number of artificial neural network algorithms could be affected while dealing with high-dimensional data. Fortunately, most real-world problem data are located in a manifold of dimension p (the data intrinsic dimension) much smaller than its raw dimension. Reducing data dimensionality to this smaller value can therefore decrease the problems related to high dimension.

In order to reduce the problem dimensionality, we use Curvilinear Distance Analysis (CDA). This technique is related to Curvilinear Component Analysis (CCA), whose goal is to reproduce the topology of a n -dimension original space in a new p -dimension space (where $p < n$) without fixing any configuration of the topology (Demartines & Hérault, 1993). To do so, a criterion characterizing the differences between original and projected space topologies is processed:

$$E_{CCA} = \frac{1}{2} \sum_i \sum_{j \neq i} (d_j^n - d_j^p)^2 F(d_j^p) \quad (1)$$

Where d_j^n (respectively d_j^p) is the Euclidean distance between vectors x_i and x_j of considered distribution in original space (resp. in projected space), and F is a decreasing function which favours local topology with respect to the global topology. This energy function is minimized by stochastic gradient descent (Demartines & Hérault, 1995):

$$\forall i \neq j, \Delta x_i^p = \alpha(t) \frac{d_{ij}^n - d_{ij}^p}{d_{ij}^p} u(\lambda(t) - d_{ij}^p) (x_i^p - x_j^p), \quad (2)$$

Where $\alpha : \mathbb{R}^+ \rightarrow [0;1]$ and $\lambda : \mathbb{R}^+ \rightarrow \mathbb{R}^+$ are two decreasing functions representing respectively a learning parameter and a neighbourhood factor. CCA provides also a similar method to project, in continuous way, new points in the original space onto the projected space, using the knowledge of already projected vectors.

But, since CCA encounters difficulties with unfolding of very non-linear manifolds, an evolution called CDA has been proposed (Lee, Lendasse, Donckers, & Verleysen, 2000). It involves curvilinear distances (in order to better approximate geodesic distances on the considered manifold) instead of Euclidean ones. Curvilinear distances are processed in two steps way. First is built a graph between vectors by considering k -NN, ε , or other neighbourhood, weighted by Euclidean distance between adjacent nodes. Then the curvilinear distance between two vectors is computed as the minimal distance between these vectors in the graph using Dijkstra's algorithm. Finally the original CCA algorithm is applied using processed curvilinear

distances. This algorithm allows dealing with very non-linear manifolds and is much more robust against the choices of α and λ functions.

It has been successfully used as a preliminary step before maximum likelihood classification in (Lennon, Mercier, Mouchot, & Hubert-Moy, 2001) and we have also showed its positive impact on neural network technique based classification performance (Voiry, Madani, Amarger, & Bernier, 2007). In this last paper, we have first demonstrated that a synthetic problem (nevertheless defined from our real industrial data) whose intrinsic dimensionality is two, is better treated by MLP after 2D dimension reduction than in its raw expression. We have also showed that CDA performs better for this problem than CCA and Self Organizing Map pre-processing.

Implementation on Industrial Optical Devices

In order to validate the above-presented concepts and to provide an industrial prototype, an automatic control system has been realized. It involves an Olympus B52 microscope combined with a Corvus stage, which allows scanning an entire optical component (presented in Figure 3). 50x magnification is used, that leads to microscopic 1.77 mm x 1.33 mm fields and 1.28 μm x 1.28 μm sized pixels. The proposed image processing method is applied on-line. A post-processing software enables to collect pieces of a defect that are detected in different microscopic fields (for example pieces of a long scratch) to form only one defect, and to compute an overall cartography of checked device (Figure 3).

These facilities were used to acquire a great number of Nomarski images, from which were extracted defects images using aforementioned technique. Two

experiments called A and B were carried out, using two different optical devices. Table 1 shows the different parameters corresponding to these experiments. It's important to note that, in order to avoid false classes learning, items images depicting microscopic field boundaries or two (or more) different defects were discarded from used database. Furthermore, studied optical devices were not specially cleaned, what accounts for the presence of some dusts and cleaning marks. Items of these two databases were labelled by an expert with two different labels: "dust" (class 1) and "other defects" (class -1). Table 1 shows also items repartition between the two defined classes.

Using this experimental set-up, classification experiment was performed. It involved a multilayer perceptron with n input neurons, 35 neurons in one hidden layer, and 2 output neurons ($n-35-2$) MLP. First this artificial neural network was trained for discrimination task between classes 1 and -1, using database B. This training phase used BFGS (Broyden, Fletcher, Goldfarb, and Shanno) with Bayesian regularization algorithm, and was achieved 5 times. Subsequently, the generalization ability of obtained neural network was processed using database A. Since database A and B issued from different optical devices, such generalization results are significant. Following this procedure, 14 different experiments were conducted with the aim of studying the global classification performance and the impact of CDA dimensionality reduction on this performance. First experiment used original Fourier-Mellin issued features (13-dimensional), the others used the same features after CDA n -dimensional space reduction (with n varying between 2 and 13). Figure 4 depicts global classification performances (calculated by averaging percentage of well-classified items for the 5 trainings) for the 14 different experiments, as well as

Figure 3. Automatic control system and cartography of a 100mm x 65mm optical device

Table 1. Description of the two databases used for validation experiments

| Database | Optical Device | Number of microscopic fields | Corresponding area | Total items number | Class 1 items number | Class -1 items number |
|----------|----------------|------------------------------|--------------------|--------------------|----------------------|-----------------------|
| A | 1 | 1178 | 28 cm ² | 3865 | 275 | 3590 |
| B | 2 | 605 | 14 cm ² | 1910 | 184 | 1726 |

Figure 4. Classification performances for different CDA issued data dimensionality. Classification performances using raw data (13-dimensional) are also depicted as dotted lines.

class 1 classification and class -1 classification performances. It shows first that equivalent performances can be obtained using only 5-dimensional data instead of unprocessed defects representations (13-dimensional). As a consequence neural architecture complexity and therefore processing time can be saved using CDA dimensionality reduction, while keeping performance level. Moreover, obtained scores are satisfactory: about 70% of “dust” defects are well-recognized (this can be enough for aimed application) as well as about 97% of other defects (the few 3% errors can however pose problems because every “permanent” defect has to be reported). Furthermore, we think that this significant performances difference between class 1 and class -1 recognition is due to the fact that class 1 is underrepresented in learning database.

FUTURE TRENDS

Next phase of this work will deal with classification tasks involving more classes. We want also use much more Fourier-Mellin invariants, because we think that it would improve classification performance by supplying additional information. In this case, CDA based dimensionality reduction technique would be a foremost step to keep reasonable classification system's complexity and processing time.

CONCLUSION

A reliable diagnosis of aesthetic flaws in high-quality optical devices is a crucial task to ensure products' nominal specification and to enhance the production quality by studying the impact of the process on such defects. To ensure a reliable diagnosis, an automatic system is needed to detect defects and secondly dis-

criminate the “false” defects (correctable defects) from “abiding” (permanent) ones. In this paper is described a complete framework, which allows detecting all defects present in a raw Nomarski image and extracting pertinent features for classification of these defects. Obtained proper performances for “dust” versus “other” defects classification task with MLP neural network has demonstrated the pertinence of proposed approach. In addition, data dimensionality reduction permits to use low complexity classifier (while keeping performance level) and therefore to save processing time.

KEY TERMS

Artificial Neural Networks: A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used

in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Backpropagation algorithm: Learning algorithm of ANNs, based on minimising the error obtained from the comparison between the outputs that the network gives after the application of a set of network inputs and the outputs it should give (the desired outputs).

Classification: Affection of a phenomenon to a predefined class or category by studying its characteristic features. In our work it consists in determining the nature of detected optical devices surface defects (for example “dust” or “other type of defects”).

Data Dimensionality Reduction: Data dimensionality reduction is the transformation of high-dimensional data into a meaningful representation of reduced dimensionality. The goal is to find the important relationships between parameters and reproduce those relationships in a lower dimensionality space. Ideally, the obtained representation has a dimensionality that corresponds to the intrinsic dimensionality of the data. Dimensionality reduction is important in many domains, since it facilitates classification, visualization, and compression of high-dimensional data. In our work it's performed using Curvilinear Distance Analysis.

Data Intrinsic Dimension: When data is described by vectors (sets of characteristic values), data intrinsic dimension is the effective number of degrees of freedom of the vectors' set. Generally, this dimension is smaller than the data raw dimension because it may exist linear and/or non-linear relations between the different components of the vectors.

Data Raw Dimension: When data is described by vectors (sets of characteristic values), data raw dimension is simply the number of components of these vectors.

Detection: Identification of a phenomenon among others from a number of characteristic features or “symptoms”. In our work, it consists in identifying surface irregularities on optical devices.

MLP (Multi Layer Perceptron): This widely used artificial neural network employs the perceptron as simple processor. The model of the perceptron, proposed by Rosenblatt is as follows:

In this diagram, the X represent the inputs and Y the output of the neuron. Each input is multiplied by the weight w , a threshold b is subtracted from the result and finally Y is processed by the application of an activation function f . The weights of the connection are adjusted during a learning phase using backpropagation algorithm.

Artificial Intelligence and Education

INTRODUCTION

Governments and institutions are facing the new demands of a rapidly changing society. Among many significant trends, some facts should be considered (Silverstein, 2006): (1) the increment of number and type of students; and (2) the limitations imposed by educational costs and course schedules. About the former, the need of a continuous update of knowledge and competences in an evolving work environment requires life-long learning solutions. An increasing number of young adults are returning to classrooms in order to finish their graduate degrees or attend postgraduate programs to achieve an specialization on a certain domain. About the later, due to the emergence of new types of students, budget constraints and schedule conflicts appear. Workers and immigrants, for instance, are relevant groups for which educational costs and job incompatible schedules could be the key factor to register into a course or to give up a program after investing time and effort on it. In order to solve the needs derived from this social context, new educational approaches should be proposed: (1) to improve and extend the online learning courses, which would reduce student costs and allows to cover the educational needs of a higher number of students, and (2) to automate learning processes, then reducing teacher costs and providing a more personalized educational experience anytime, anywhere.

As a result of this context, in the last decade an increasing interest on applying computer technologies in the field of Education has been observed. On this regard, the paradigms of the Artificial Intelligence (AI) field are attracting an special attention to solve the issues derived from the introduction of computers as supporting resources of different learning strategies. In this paper we review the state-of-art of the application of Artificial Intelligence techniques in the field of Education, focusing on (1) the most popular educa-

tional tools based on AI, and (2) the most relevant AI techniques applied on the development of intelligent educational systems.

EXAMPLES OF EDUCATIONAL TOOLS BASED ON AI

The field of Artificial Intelligence can contribute with interesting solutions to the needs of the educational domain (Kennedy, 2002). In what follows, the type of systems that can be built based on AI techniques are outlined.

Intelligent Tutoring Systems

The Intelligent Tutoring Systems are applications that provide personalized/adaptive learning without the intervention of human teachers (VanLehn, 2006). They are constituted by three main components: (1) knowledge of the educational contents, (2) knowledge of the student, and (3) knowledge of the learning procedures and methodologies. These systems promise to radically transform our vision of online learning. As opposed to the hypertext-based e-learning applications, which provide the students with a certain number of opportunities to search for the correct answer before showing it, the intelligent tutoring systems perform like coaches not only after the introduction of the response, but also offering suggestions when the students doubt or are blocked during the process of solving the problem. In this way, the assistance guide the learning process rather than merely saying what is correct or what is wrong.

There exist numerous examples of intelligent tutoring systems, some of them developed at universities as research projects while others created with business goals. Among the first ones, the *Andes* systems (VanLehn, Lynch, Schulze, Shapiro, Shelby, Taylor, Treacy,

Weinstein & Wintersgill, 2005), developed under the guidance of Kurt VanLehn of the University of Pittsburg, is a popular example. The system is in charge of guiding the students while they try to solve different sets of problems and exercises. When the student ask for help in the middle of an activity, the system either provides hints in order to step further towards the solution or points out what was wrong in some earlier step. *Andes* was successfully evaluated during 5 years in the Naval Academy of the United States and can be downloaded for free. Another relevant system is *Cognitive Tutor* (Koedinger, Anderson, Hadley & Mark, 1997), is a comprehensive secondary mathematics curricula and computer-based tutoring program developed by John R. Anderson, professor at the Carnegie Mellon University. The Cognitive Tutor is an example of how research prototypes can be evolved into commercial solutions, as it is nowadays used in 1,500 schools in the United States. On the business side, Read-On! is presented as a product that teaches reading comprehension skills for adults. It analyzes and diagnoses the specific deficiencies and problems of each student and then adapts the learning process based on that features (Read On, 2007). It includes an authoring tool that allows course designers to adapt course contents to different student profiles in a fast and flexible way.

Automatic Evaluation Systems

Automatic Evaluation Systems are mainly focused on evaluating the strengths and weaknesses of students in different learning activities through assessment tests (Conejo, Guzmán, Millan, Trella, Perez-de-la-Cruz. & Rios, 2004). In this way, these systems not only perform the automatic correction of the test, but also derive automatically useful information about the competences and skills obtained by the students during the educational process.

Among the automatic evaluation systems, we could highlight *ToL* (Test On Line) (Tartaglia & Tresso, 2002), which have been used by Physics students in the Polytechnic University of Milano. The system is composed of a database of tests, an algorithm for question selection, and a mechanism for the automatic evaluation of tests, which can be additionally configured by the teachers. *CELLA* (Comprehensive English Language Learning Assesment) (Cella, 2007) is another system that evaluates the student competence on using and understanding the English language. The application

shows the progress carried out by the students and determines their proficiency and degree of competence on the use of foreign languages. As for commercial applications, *Intellimetric* is a Web-based system that lets students to submit their work online (Intellimetric, 2007). In a few seconds, the AI-supported grading engine automatically provides the score of the work. The company claims a reliability of 99%, meaning that 99 percent of the time the engine's scores match those provided by human teachers.

Computer Supported Collaborative Learning

The environments of computer supported collaborative learning are aimed at facilitating the learning process providing the students both the context and tools to interact and work in a collaborative way with their classmates (Soller, Martinez, Jermann & Muehlenbrock, 2005). In intelligent-based systems, the collaboration is usually carried out with the help of software agents in charge of mediating and supporting student interaction to achieve the proposed learning objectives.

The research prototypes are the suitable test-beds to prove new ideas and concepts, to provide the best collaborative strategies. The *DEGREE* system, for instance, allows the characterization of group behaviours as well as the individual behaviours of the people constituting them, on the basis of a set of attributes or tags. The mediator agent utilizes those attributes, which are introduced by students, in order to provide recommendations and suggestions to improve the interaction inside each group (Barros & Verdejo, 2000). In the business domain there exist multiple solutions although they do not offer intelligent mediation to facilitate the collaborative interactions. The *DEBBIE* system (DePauw Electronic Blackboard for Interactive Education) is one of the most popular (Berque, Johnson, Hutcheson, Jovanovic, Moore, Singer & Slattery, 2000). It was originally developed at the beginning of year 2000 at the University of Depauw, and managed later by the DyKnow company, which was specifically created to make profit with *DEBBIE* (Schnitzler, 2004). The technology that currently offers DyKnow allows both teachers and students to instantaneously share information and ideas. The final goal is to support student tasks in the classroom by eliminating the need of performing simple tasks, as for instance backing up the teacher's presentations. The students could therefore

be more focused on understanding as well as analyzing the concepts presented by the teacher.

Game-Based Learning

Learning based on serious games, a term coined to distinguish between learning-oriented games used in education and purely entertaining-oriented games, deal with the utilization of the motivational power and attractiveness of games in the educational domain in order to improve the satisfaction and performance of students when acquiring new knowledge and skills. This type of learning allows to carry out activities in complex educational environments that would be impossible to implement, because of budget, time, infrastructure and security limitations, with traditional resources (Michael & Chen, 2005; Corti, 2006).

NetAid's is an institution that develop games to teach concepts of global citizenship and to sensitize to fight against poverty. One of its first games, released in 2002, called *NetAid World Class*, consists on taking the identity of a real child living in India and to resolve the real problems that confront the poor children in this region (Stokes, 2005). In 2003 the game was used by 40.000 students in different Schools across the United States. In the business and entertainment arena, many games exist that can be resorted to reach educational goals. Among the most popular ones, *Brain Training* of Nintendo (Brain Training, 2007) challenges the user to improve her mental shape by doing memory, reasoning and mathematical exercises. The final goal is to reach an optimal cerebral age after some regular training.

AI TECHNIQUES IN EDUCATION

The intelligent educational systems reviewed above are based on a diversity of artificial intelligence techniques (Brusilovsky & Peylo, 2003). The most frequently used in the field of education are: (1) personalization mechanisms based on student and group models, (2) intelligent agents and agent-based systems, and (3) ontologies and semantic web techniques.

Personalization Mechanisms

The personalization techniques, which are the basis of intelligent tutoring systems, involve the creation and

use of student models. Broadly speaking, these models imply the construction of a qualitative representation of student behavior in terms of existing background knowledge about a domain (McCalla, 1992). These representations can be further used in intelligent tutoring systems, intelligent learning environments, and to develop autonomous intelligent agents that may collaborate with human students during the learning process. The introduction of machine learning techniques facilitates to update and extend the first versions of student models in order to adapt to the evolution of each student as well as the possible changes and modifications of contents and learning activities (Sison & Shimura, 1998). The most popular student modeling techniques are (Beck, Stern, & Haugsjaa, 1996): overlay models and bayesian network models. The first method consists on considering the student model as a subset of the knowledge of an expert in the domain on which the learning is taking place. In fact, the degree of learning is measured in terms of the comparison between the knowledge acquired and represented in the student model with the background initially stored in the expert model. The second method deals with the representation of the learning process as a network of knowledge states. Once defined, the model should infer, from the tutor-student interaction, the probability of the student on being in a certain state.

Intelligent Agents and Agent-Based Systems

Software agents are considered software entities, such as software programs or robots, that present, with different degree, three main attributes: autonomy, cooperation and learning (Nwana, 1996). Autonomy refers to the principle that an agent can operate on their own (acting and deciding upon its own representation of the world). Cooperation refers to the ability to interact with other agents via some communication language. Finally, learning is essential to react or interact with the external environment. Teams of intelligent agents build up MultiAgent Systems (MAS). In this type of systems each agent has either incomplete information or limited capabilities for solving the problem at hand. Other important aspect concerns with the lack of centralized global control; therefore, data is distributed all over the system and computation is asynchronous (Sycara, 1998). Many important tasks can be carried out by intelligent agents in the context of learning and

educational systems (Jafari, 2002, Sánchez, Lama, Amorim, Riera, Vila & Barro, 2003): the monitoring of inputs, outputs, and the activity outcomes produced by the students; the verification of deadlines during homework and exercise submission; automatic answering of student questions; and the automatic grading of tests and surveys.

Ontologies and Semantic Web Techniques

Ontologies aim to capture and represent consensual knowledge in a generic way, and that they may be reused and shared across software applications (Gómez-Pérez, Fernández-López & Corcho, 2004). An ontology is composed of concepts or classes and their attributes, the relationships between concepts, the properties of these relationships, and the axioms and rules that explicitly represents the knowledge of a certain domain. In the educational domain, several ontologies have been proposed: (1) to describe the learning contents of technical documents (Kabel, Wielinga, & de How, 1999), (2) to model the elements required for the design, analysis, and evaluation of the interaction between learners in computer supported cooperative learning (Inaba, Tamura, Ohkubo, Ikeda, Mizoguchi & Toyoda, 2001), (3) to specify the knowledge needed to define new collaborative learning scenarios (Barros, Verdejo, Read & Mizoguchi, 2002), (4) to formalize the semantics of learning objects that are based on metadata standards (Brase & Nejd, 2004), and (5) to describe the semantics of learning design languages (Amorim, Lama, Sánchez, Riera & Vila, 2006).

FUTURE TRENDS

The next generation of adaptive environments will integrate pedagogical agents, enriched with data mining and machine learning techniques, capable of providing cognitive diagnosis of the learners that will help to determine the state of the learning process and then optimize the selection of personalized learning designs. Moreover, improved models of learners, facilitators, tasks and problem-solving processes, combined with the use of Ontologies and reasoning engines, will facilitate the execution of learning activities on either online platforms or traditional classroom settings.

Research in this field is very active and faces ambitious goals. In some decades it could be possible to dream about sci-fi environments in which the students would have brain interfaces to directly interact with an intelligent assistant (Koch, 2006), which would play the role of a tutor with a direct connection with learning areas of the brain.

CONCLUSION

In this paper we have reviewed the state-of-art of the application of Artificial Intelligence techniques in the field of Education. AI approaches seem promising to improve the quality of the learning process and then to satisfy the new requirements of a rapidly changing society. Current AI-based systems such as intelligent tutoring systems, computer supported collaborative learning and educational games have already proved the possibilities of applying AI techniques. Future applications will both facilitate personalized learning styles and help the tasks of teachers and students in traditional classroom settings.

KEY TERMS

Automatic Evaluation Systems: Applications focused on evaluating the strengths and weaknesses of students in different learning activities through assessment tests.

Computer Supported Collaborative Learning (CSCL): A research topic on supporting collaborative learning methodologies with the help of computers and collaborative tools.

Game-Based Learning: A new type of learning that combines educational content and computer games in order to improve the satisfaction and performance of students when acquiring new knowledge and skills.

Intelligent Tutoring Systems: A computer program that provides personalized/adaptive instruction to students without the intervention of human beings.

Ontologies: A set of concepts within a domain that capture and represent consensual knowledge in a generic way, and that they may be reused and shared across software applications.

Software Agents: Software entities, such as software programs or robots, characterized by their autonomy, cooperation and learning capabilities.

Student Models: Representation of student behavior and degree of competence in terms of existing background knowledge about a domain.

Artificial Intelligence and Rubble–Mound Breakwater Stability

INTRODUCTION

Breakwaters are coastal structures constructed to shelter a harbour basin from waves. There are two main types: rubble-mound breakwaters, consisting of various layers of stones or concrete pieces of different sizes (weights), making up a porous mound; and vertical breakwaters, impermeable and monolithic, habitually composed of concrete caissons. This article deals with rubble-mound breakwaters.

A typical rubble-mound breakwater consists of an armour layer, a filter layer and a core. For the breakwater to be stable, the armour layer units (stones or concrete pieces) must not be removed by wave action. Stability is basically achieved by weight. Certain types of concrete pieces are capable of achieving a high degree of interlocking, which contributes to stability by impeding the removal of a single unit.

The forces that an armour unit must withstand under wave action depend on the hydrodynamics on the breakwater slope, which are extremely complex due to wave breaking and the porous nature of the structure. A detailed description of the flow has not been achieved until now, and it is unclear whether it will be in the future in view of the turbulent phenomena involved. Therefore the instantaneous force exerted on an armour unit is not, at least for the time being, amenable to determination by means of a numerical model of the flow. For this reason, empirical formulations are used in rubble-mound design, calibrated on the basis of laboratory tests of model structures. However, these formulations cannot take into account

all the aspects affecting the stability, mainly because the inherent complexity of the problem does not lend itself to a simple treatment. Consequently the empirical formulations are used as a predesign tool, and physical model tests in a wave flume of the particular design in question under the pertinent sea climate conditions are *de rigueur*, except for minor structures. The physical model tests naturally integrate all the complexity of the problem. Their drawback lies in that they are expensive and time consuming.

In this article, Artificial Neural Networks are trained and tested with the results of stability tests carried out on a model breakwater. They are shown to reproduce very closely the behaviour of the physical model in the wave flume. Thus an ANN model, if trained and tested with sufficient data, may be used in lieu of the physical model tests. A virtual laboratory of this kind will save time and money with respect to the conventional procedure.

BACKGROUND

Artificial Neural Networks have been used in civil engineering applications for some time, especially in Hydrology (Ranjithan et al., 1993; Fernando and Jayawardena, 1998; Govindaraju and Rao, 2000; Maier and Dandy, 2000; Dawson and Wilby, 2001; Cigizoglu, 2004); some Ocean Engineering issues have also been tackled (Mase et al., 1995; Tsai et al., 2002; Lee and Jeng, 2002; Medina et al., 2003; Kim and Park, 2005; Yagci et al., 2005). Rubble-mound breakwater stabil-

ity is studied in Mase et al.'s (1995) pioneering work, focusing on a particular stability formula. Medina et al. (2003) train and test an Artificial Neural Network with stability data from six laboratories. The inputs are the relative wave height, the Iribarren number and a variable representing the laboratory. Kim and Park (2005) compare different ANN models on an analysis revolving around one empirical stability formula, as did Mase et al.'s (1995). Yagci et al. (2005) apply different kinds of neural networks and fuzzy logic, characterising the waves by their height, period and steepness.

PHYSICAL MODEL AND ANN MODEL

The Artificial Neural Networks were trained and tested on the basis of laboratory tests carried out in a wave flume of the CITEEC Laboratory, University of La Coruña. The flume section is 4 m wide and 0.8 m high, with a length of 33 m (Figure 1). Waves are generated by means of a piston-type paddle, controlled by an Active Absorption System (AWACS) which ensures that the waves reflected by the model are absorbed at the paddle.

The model represents a typical three-layer rubble-mound breakwater in 15 m of water, crowned at +9.00 m, at a 1:30 scale. Its slopes are 1:1.50 and 1:1.25

on the seaward and leeward sides, respectively. The armour layer consists in turn of two layers of stones with a weight $W=69 \text{ g} \pm 10\%$; those in the upper layer are painted in blue, red and black following horizontal bands, while those in the lower layer are painted in white, in order to easily identify after a test the damaged areas, *i.e.*, the areas where the upper layer has been removed. The filter layer is made up of a gravel with a median size $D_{50} = 15.11 \text{ mm}$ and a thickness of 4 cm. Finally, the core consists of a finer gravel, with $D_{50} = 6.95 \text{ mm}$, $D_{15} = 5.45 \text{ mm}$, and $D_{85} = 8.73 \text{ mm}$, and a porosity $n = 42\%$. The density of the stones and gravel is $\gamma_r = 2700 \text{ kg/m}^3$.

Waves were measured at six different stations along the longitudinal, or x-axis, of the flume. With the origin of x located at the rest position of the wave paddle, the first wave gauge, S1, was located at $x=7.98 \text{ m}$. A group of three sensors, S2, S3 and S4, was used to separate the incident and the reflected waves. The central wave gauge, S3, was placed at $x=12.28 \text{ m}$, while the position of the others, S2 and S4, was varied according to the wave generation period of each test (Table 1). Another wave gauge, S5, was located 25 cm in front of the model breakwater toe, at $x=13.47 \text{ m}$, and 16 cm to the right (as seen from the wave paddle) of the flume centreline, so as not to interfere with the video recording of the

Figure 1. Experimental set-up

Table 1. Relative water depth (kh), wave period (T), and separation between sensors S2, S3 and S4 in the stability tests

| Test key | kh | T (s) | S2-S3 (cm) | S3-S4 (cm) |
|----------|------|---------|------------|------------|
| T10, T20 | 0.98 | 1.65 | 35 | 55 |
| T11, T21 | 1.36 | 1.3 | 20 | 30 |
| T12, T22 | 1.68 | 1.13 | 20 | 30 |
| T13, T23 | 1.97 | 1.03 | 20 | 30 |

tests. Finally, a wave gauge (S6) was placed to the lee of the model breakwater, at $x=18.09$ m.

Both regular and irregular waves were used in the stability tests. This article is concerned with the eight regular wave tests, carried out with four different wave periods. The water depth in the flume was kept constant throughout the tests ($h=0.5$ m). Each test consisted of a number of wave runs with a constant value of the wave period T , related to the wavenumber k by

$$T = 2\pi \left[gk \tanh(kh) \right]^{-\frac{1}{2}},$$

where g is the gravitational acceleration. The wave periods and relative water depths (kh) of the tests are shown in Table 1.

Each wave run consisted of 200 waves. In the first run of each test, the generated waves had a model height $H=6$ cm (corresponding to a wave height in the prototype $H_p=1.80$ m); in the subsequent runs, the wave height was increased in steps of 1 cm (7 cm, 8 cm, 9 cm, etc.), so that the model breakwater was subject to ever more energetic waves.

Four damage levels (Losada *et al.*, 1986) were used to characterize the stability situation of the model breakwater after each wave run:

- (0) No damage. No armour units have been moved from their positions.
- (1) Initiation of damage. Five or more armour units have been displaced.
- (2) Iribarren damage. The displaced units of the armour's first (outer) layer have left uncovered an area of the second layer large enough for a stone to be removed by waves.
- (3) Initiation of destruction. The first unit of the armour's second layer has been removed by wave action.

As the wave height was increased through a test, the damage level also augmented from the initial 'no damage' to 'initiation of damage', 'Iribarren damage', and eventually 'initiation of destruction', at which point the test was terminated and the model rebuilt for the following test. The number of wave runs in a test varied from 10 to 14.

The foregoing damage levels provide a good semi-quantitative assessment of the breakwater stability condition. However, the following nondimensional

damage parameter is more adequate for the Artificial Neural Network model:

$$S = \frac{nD_{50}}{(1-p)b}$$

where D_{50} is the median size of the armour stones, p is the porosity of the armour layer, b is the width of the model breakwater, and n is the number of units displaced after each wave run. In this case, $D_{50}=2.95$ cm, $p=0.40$, and $b=50$ cm.

The incident wave height was nondimensionalized by means of the zero-damage wave height of the SPM (1984) formulation,

$$H_0 = \left(\frac{W K_D \left(\frac{\gamma_r}{\gamma_w} - 1 \right)^3 \cot \alpha}{\gamma_r} \right)^{\frac{1}{3}}$$

where $K_D=4$ is the stability coefficient, $\gamma_w=1000$ kg/m³ is the water density (freshwater used in the laboratory tests), and α is the breakwater slope. With these values, $H_0=9.1$ cm. The nondimensional incident wave height is given by

$$H^* = \frac{H}{H_0}$$

where H stands for the incident wave height.

Most of the previous applications of Artificial Neural Networks in Civil Engineering use multilayer feedforward networks trained with the backpropagation algorithm (Freeman and Skapura, 1991; Johansson *et al.*, 1992), which will also be employed in this study; their main advantage lies in their generalisation capabilities. Thus this kind of network may be used, for instance, to predict the armour damage that a model breakwater will sustain under certain conditions, even if these conditions were not exactly part of the data set with which the network was trained. However, the parameters describing the conditions (e. gr., wave height and period) must be within the parameter ranges of the stability tests with which the ANN was trained.

In this case, the results from the stability tests of the model rubble-mound breakwater described above were used to train and test the Artificial Neural Network. The eight stability tests comprised 96 wave runs. The input to the network was the nondimensional wave height (H^*) and the relative water depth (kh) of a wave run, and the output, the resulting nondimensional damage parameter (S). Data from 49 wave runs, corresponding to the four stability tests T20, T21, T22, and T23, were used for training the network; while data from 46 wave runs, pertaining to the remaining four tests (T10, T11, T12, and T13) were used for testing it. This distribution of data made sure that each of the four wave generation periods (Table 1) was present in both the training and the testing data sets.

First, an Artificial Neural Network with 10 sigmoid neurons in the hidden layer and a linear output layer was trained and tested 10 times. The ANN was trained by means of the Bayesian Regularisation method (MacKay, 1992), known to be effective in avoiding overfitting. The average MSE values were 0.2880 considering all the data, 0.2224 for the training data set, and 0.3593 for the testing data set. The standard deviations of the MSE values were 5.9651×10^{-10} , 9.0962×10^{-10} , and 7.7356×10^{-10} , for the complete data set, the training and the testing data sets, respectively. Increasing the number of neural units in the hidden layer to 15 did not produce any significant improvement in the average MSE values (0.2879, 0.2222 and 0.3593 for all the data, the training data set and the testing data set, respectively), so the former Artificial Neural Network, with 10 neurons in the hidden layer, was retained.

The following results correspond to a training and testing run of this ANN with a global MSE of 0.2513. The linear regression analysis indicates that the ANN data fit very well to the experimental data over the whole range of the nondimensional damage parameter S . In effect, the correlation coefficient is 0.983, and the equation of the best linear fit, $y = 0.938x - 0.00229$, is very close to that of the diagonal line $y = x$ (Figure 2).

The results obtained with the training data set (stability tests T20, T21, T22 and T23) show an excellent agreement between the ANN model and the physical model (Figure 3). In three of the four tests (T20, T22 and T23) the ANN data mimic the measurements on the model breakwater almost to perfection. In test T21, the physical model experiences a brusque increase in the damage level at $H^* = 1.65$, which is slightly softened by the ANN model. The MSE value is 0.1441.

Figure 2. Regression analysis. Complete data set.

The testing data set comprised also four stability tests (T10, T11, T12 and T13). The inherent difficulty of the problem is apparent in test T11 (Figure 4), in which the nondimensional damage parameter (S) does not increase in the wave run at $H^* = 1.54$, but suddenly soars by about 100% in the next wave run, at $H^* = 1.65$. Such differences from one wave run to the next are practically impossible to capture by the ANN model, given that the inputs to the ANN model either vary only slightly, by less than 7% in this case (the nondimensional wave height, H^*) or do not vary at all (the relative water depth, kh). It should be remembered that, when computing the damage after a given wave run, the ANN does not have any information about the damage level before that wave run, unlike the physical model. Yet the ANN performs well, yielding an MSE value of 0.3678 with the testing data set.

FUTURE TRENDS

In this study, results from stability tests carried out with regular waves were used. Irregular wave tests should also be analyzed by means of Artificial Intelligence, and it is the authors' intention to do so in the future. Breakwater characteristics are another important aspect of the problem. The ANN cannot extrapolate beyond the ranges of wave and breakwater characteristics on which it was trained. The stability tests used for this

Figure 3. ANN (\square) and physical model results (o) for the stability tests T20, T21, T22 and T23 (training data set)

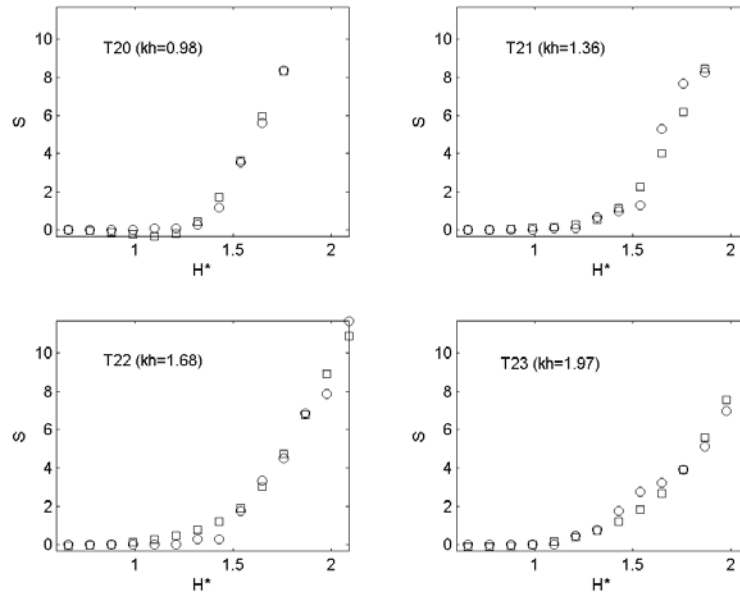

Figure 4. ANN (\square) and physical model results (o) for the stability tests T10, T11, T12 and T13 (testing data set)

study considered one model breakwater; further tests involving physical models with other geometries and materials should be undertaken. Once the potential of Artificial Neural Networks to model the behaviour of a rubble-mound breakwater subject to wave action has been proven, a virtual laboratory could be constructed with the results from these tests.

CONCLUSION

This article shows that Artificial Neural Networks are capable of modelling the behaviour of a model rubble-mound breakwater in the face of energetic waves. This is a very complex problem for a number of reasons. In the first place, the hydrodynamics of waves breaking on a slope are not well known, so much so that a detailed characterization of the motions of the water particles is not possible for the time being, and may remain so in the future due to the chaotic nature of the processes involved. Second, in the case of a rubble-mound breakwater the problem is further compounded by the porous nature of the structure, which brings about a complex wave-structure interaction in which the flux of energy carried by the incident wave is distributed into the following processes: (i) wave reflection; (ii) wave breaking on the slope; (iii) wave transmission through the porous medium; and (iv) dissipation. The subtle interplay between all these processes means that it is not possible to study one of them without taking the others into account. Third, the porous medium itself is of a stochastic nature: no two rubble-mound breakwaters can be said to be identical. This complexity has precluded up to now the development of a numerical model which can reliably analyse the forces acting on the armour layer units and hence the stability situation of the breakwater. As a consequence, physical model tests are a necessity whenever a major rubble-mound structure is envisaged.

Notwithstanding the difficulty of the problem, the Artificial Neural Network used in this work has been shown to reproduce very closely the physical model results. Thus, an Artificial Neural Network can constitute, once properly trained and validated, a virtual laboratory. Testing a breakwater in this virtual laboratory is much quicker and far less expensive than testing a physical model of the same structure in a laboratory wave flume.

KEY TERMS

Armour Damage: Extraction of stones or concrete units from the armour layer by wave action.

Armour Layer: Outer layer of a rubble-mound breakwater, consisting of heavy stones or concrete blocks.

Artificial Neural Networks: Interconnected set of many simple processing units, commonly called neurons, that use a mathematical model representing an input/output relation.

Backpropagation Algorithm: Supervised learning technique used by ANNs that iteratively modifies the weights of the connections of the network so the error given by the network after the comparison of the outputs with the desired one decreases.

Breakwater: Coastal structure built for sheltering an area from waves, usually for loading or unloading vessels.

Reflection: The process by which the energy of the incoming waves is returned seaward.

Significant Wave Height: In wave record analysis, the average height of the highest one-third of a selected number of waves.

Artificial Intelligence for Information Retrieval

A

Thomas Mandl

University of Hildesheim, Germany

INTRODUCTION

This article describes the most prominent approaches to apply artificial intelligence technologies to **information retrieval** (IR). **Information retrieval** is a key technology for knowledge management. It deals with the search for information and the representation, storage and organization of knowledge. **Information retrieval** is concerned with search processes in which a user needs to identify a subset of information which is relevant for his information need within a large amount of knowledge. The information seeker formulates a query trying to describe his information need. The query is compared to document representations which were extracted during an **indexing** phase. The representations of documents and queries are typically matched by a similarity function such as the Cosine. The most similar documents are presented to the users who can evaluate the relevance with respect to their problem (Belkin, 2000). The problem to properly represent documents and to match imprecise representations has soon led to the application of techniques developed within Artificial Intelligence to information retrieval.

BACKGROUND

In the early days of computer science, **information retrieval** (IR) and artificial intelligence (AI) developed in parallel. In the 1980s, they started to cooperate and the term intelligent **information retrieval** was coined for AI applications in IR. In the 1990s, **information retrieval** has seen a shift from set based Boolean retrieval models to **ranking** systems like the vector space model and **probabilistic** approaches. These approximate reasoning systems opened the door for more intelligent value added components. The large amount of text documents available in professional databases and on the internet has led to a demand for intelligent methods in text retrieval and to considerable research in this area. The need for better preprocessing to extract more knowledge from data has become an

important way to improve systems. Off the shelf approaches promise worse results than systems adapted to users, domain and information needs. Today, most techniques developed in AI have been applied to retrieval systems with more or less success. When data from users is available, systems use often machine learning to optimize their results.

Artificial Intelligence Methods in Information Retrieval

Artificial intelligence methods are employed throughout the standard **information retrieval** process and for novel value added services. The first section gives a brief overview of information retrieval. The subsequent sections are organized along the steps in the retrieval process and give examples for applications.

Information Retrieval

Information retrieval deals with the storage and **representation** of knowledge and the retrieval of information relevant for a specific user problem. The information seeker formulates a query trying to describe his information need. The query is compared to document **representations**. The representations of documents and queries are typically matched by a similarity function such as the Cosine or the Dice coefficient. The most similar documents are presented to the users who can evaluate the relevance with respect to their problem.

Indexing usually consists of the several phases. After word segmentation, stopwords are removed. These common words like articles or prepositions contain little meaning by themselves and are ignored in the document **representation**. Second, word forms are transformed into their basic form, the stem. During the **stemming** phase, e.g. houses would be transformed into house. For the document **representation**, different word forms are usually not necessary. The importance of a word for a document can be different. Some words better describe the content of a document than others.

This weight is determined by the frequency of a stem within the text of a document (Savoy, 2003).

In multimedia retrieval, the context is essential for the selection of a form of query and document **representation**. Different media **representations** may be matched against each other or transformations may become necessary (e.g. to match terms against pictures or spoken language utterances against documents in written text).

As **information retrieval** needs to deal with vague knowledge, exact processing methods are not appropriate. Vague retrieval models like the **probabilistic** model are more suitable. Within these models, terms are provided with weights corresponding to their importance for a document. These weights mirror different levels of relevance.

The result of current **information retrieval** systems are usually sorted lists of documents where the top results are more likely to be relevant according to the system. In some approaches, the user can judge the documents returned to him and tell the systems which ones are relevant for him. The system then resorts the result set. Documents which contain many of the words present in the relevant documents are ranked higher. This relevance feedback process is known to greatly improve the performance. Relevance feedback is also an interesting application for machine learning. Based on a human decisions, the optimization step can be modeled with several approaches, e.g. with rough sets (Singh & Dey 2005). In Web environments, a click is often interpreted as an implicit positive relevance judgment (Joachims & Radlinski, 2007).

Advanced Representation Models

In order to represent documents in natural language, the content of these documents needs to be analyzed. This is a hard task for computer systems. Robust semantic analysis for large text collections or even multimedia objects has yet to be developed. Therefore, text documents are represented by natural language terms mostly without syntactic or semantic context. This is often referred to as the bag-of-words approach. These keywords or terms can only imperfectly represent an object because their context and relations to other terms are lost.

However, great progress has been made and systems for semantic analysis are getting competitive. Advanced syntactic and semantic parsing for robust processing

of mass data has been derived from computational linguistics (Hartrumpf, 2006).

For application and domain specific knowledge, another approach is taken to improve the **representation** of documents. The **representation** scheme is enriched by exploiting knowledge about concepts of the domain (Lin & Demner-Fushman, 2006).

Match Between Query and Document

Once the **representation** has been derived, a crucial aspect of an **information retrieval** system is the similarity calculation between query and document **representation**. Most systems use mathematical similarity functions such as the Cosine. The decision for a specific function is based on heuristics or empirical evaluations. Several approaches use machine learning for long term optimization of the matching between term and document. E.g. one approach applies genetic algorithm to adapt a weighting function to a collection (Almeida et al., 2007).

Neural networks have been applied widely in IR. Several network architectures have been applied for retrieval tasks, most often the so-called spreading activation networks are used. Spreading activation networks are simple Hopfield-style networks, however, they do not use the learning rule of Hopfield networks. They typically consist of two layers representing terms and documents. The weights of connections between the layers are bi-directional and initially set according to the results of the traditional **indexing** and weighting algorithms (Belkin, 2000). The neurons corresponding to the terms of the user's query are activated in the term layer and activation spreads along the weights into the document layer and back. Activation represents relevance or interest and reaches potentially relevant terms and documents. The most highly activated documents are presented to the user as result. A closer look at the models reveals that they very much resemble the traditional vector space model of **Information Retrieval** (Mandl, 2000). It is not until after the second step that associative nature of the spreading activation process leads to results different from a vector space model. The spreading activation networks successfully tested with mass data do not take advantage of this associative property. In some systems the process is halted after only one step from the term layer into the document layer, whereas others make one more step

back to the term layer to facilitate learning (Kwok & Grunfeld, 1996).

Queries in **information retrieval** systems are usually short and contain few words. Longer queries have a higher probability to achieve good results. As a consequence, systems try to add good terms to a query entered by a user. Several techniques have been applied. Either these terms are taken from top ranked documents or terms similar to the original ones are used. Another technique is to use terms from documents from the same category. For this task, classification algorithms from machine learning are used (Sebastiani, 2002).

Link analysis applies well known measures from bibliometric analysis to the Web. The number links pointing to a Web page is used as an indicator for its quality (Borodin et al., 2005). PageRank assigns an authority value to each Web page which is primarily a function of its back links. Additionally, it assumes that links from pages with high authority should be weighed higher and should result in a higher authority for the receiving page. To account for the different values each page has to distribute, the algorithm is carried out iteratively until the result converges (Borodin et al., 2005). Machine Learning approaches complement link analysis. Decisions of humans about the quality of Web pages are used to determine design features of these pages which are good indicators of their quality. Machine learning models are applied to determine the quality of pages not judged yet (Mandl, 2006, Marti & Hearst, 2002).

Learning from users has been an important strategy to improve systems. In addition to the content, artificial intelligence methods have been used to improve the user interface.

Value Added Components for User Interfaces

Several Researchers have implemented **information retrieval** systems based on the Kohonen **self organizing map** (SOM), a neural network model for unsupervised classification. They provide an associative user interface where neighborhood of documents expresses a semantic relation. Implementations for large collections can be tested on the internet (Kohonen, 1998). The SOM consists of a usually two-dimensional grid of neurons, each associated with a weight vector. Input documents are classified according to the similarity between the input pattern and the weight vectors, and,

the algorithm adapts the weights of the winning neuron and its neighbor. In that way, neighboring clusters have a high similarity.

The **information retrieval** applications of SOMs classify documents and assign the dominant term as name for the cluster. For real world large scale collections, one two-dimensional grid is not sufficient. It would be either too big or each node would contain too many documents consequently. Neither would be helpful for users, therefore, a layered architecture is adopted. The highest layer consists of nodes which represent clusters of documents. The documents of these nodes are again analyzed by a SOM. For the user, the system consists of several two-dimensional maps of terms where similar terms are close to each other. After choosing one node, he may reach another two-dimensional SOM.

The **information retrieval** paradigm for the SOM is browsing and navigating between layers of maps. The SOM seems to be a very natural visualization. However, the SOM approach has some serious drawbacks.

- The interface for interacting with several layers of maps makes the system difficult to browse.
- Users of large text collections need primarily search mechanisms which the SOM itself does not offer.
- The similarity of the document collection is reduced to two dimensions omitting many potentially interesting aspects.
- The SOM unfolds its advantages for human-computer-interaction better for a small number of documents. A very encouraging application would be the clustering of the result set. The neurons would fit on one screen, the number of terms would be limited and therefore, the reduction to two dimensions would not omit so many aspects.

User Classification and Personalization

Adaptive **information retrieval** approaches intend to tailor the results of a system to one user and his interests and preferences. The most popular **representation** scheme relies on the **representation** scheme used in **information retrieval** where a document-term-matrix stores the importance or weight of each term for each document. When a term appears in a document, this weight should be different from zero. User interest can

also be stored like a document. Then the interest is a vector of terms. These terms can be ones that a user has entered or selected in a user interface or which the system has extracted from documents for which the user has shown interest by viewing or downloading them (Agichtein et al., 2006).

An example for such a system is UCAIR which can be installed as a browser plugin. UCAIR relies on a standard web search engine to obtain a search result and a primary ranking. This **ranking** is now being modified by re-**ranking** the documents based on implicit feedback and a stored user interest profile (Shen et al., 2005).

Most systems use this method of storing the user interest in a term vector. However, this method has several drawbacks. The interest profile may not be stable and the user may have a variety of diverging interests for work and leisure which are mixed in one profile.

Advanced **individualization** techniques personalize the underlying system functions. The results of empirical studies have shown that relevance feedback is an effective technique to improve retrieval quality. Learning methods for **information retrieval** need to extend the range of relevance feedback effects beyond the modification of the query in order to achieve long-term adaptation to the subjective point of view of the user. The mere change of the query often results in improved quality; however, the information is lost after the current session.

Some systems change the document **representation** according to the relevance feedback information. In a vector space metaphor, the relevant documents are moved toward the query **representation**. This approach also comprises some problems. Because only a fraction of the documents are affected by the modifications, the basic data from the **indexing** process is changed to a somewhat heterogeneous state. The original **indexing** result is not available anymore.

Certainly, this technique is inadequate for fusion approaches where several retrieval methods are combined. In this case, several basic **representations** would need to be changed according to the influence of the corresponding methods on the relevant documents. The indexes are usually heterogeneous, which is often considered an advantage of fusion approaches. A high computational overload would be the consequence.

The MIMOR (Multiple Indexing and Method-Object Relations) approach does not rely on changes to the document or the query **representation** when processing

relevance feedback information for personalization. Instead, it focuses on the central aspect of a retrieval function, the calculation of the similarity between document and query. Like other fusion methods, MIMOR accepts the result of individual retrieval systems like from a black box. These results are fused by a linear combination which is stored during many sessions. The weights for the systems experience a change through learning. They adapt according to relevance feedback information provided by users and create a long-term model for future use. That way, MIMOR learns which systems were successful in the past (Mandl & Womser-Hacker, 2004).

FUTURE TRENDS

Information retrieval systems are applied in more and more complex and diverse environments. Searching e-mail, social computing collections and other specific domains pose new challenges which lead to innovative systems. These retrieval applications require thorough and user oriented evaluation. New evaluation measures and standardized test collections are necessary to achieve reliable evaluation results.

In user adaptation, recommendation systems are an important trend for future improvement. Recommendation systems need to be seen in the context of social computing applications. System developers face the growth of user generated content which allows new reasoning methods.

New application like question answering relying on more intelligent processing can be expected to gain more market share in the near future (Hartrumpf, 2006)

CONCLUSION

Knowledge management is of main importance for the information society. Documents written in natural language contain an important share of the knowledge available. Consequently, retrieval is crucial for the success of knowledge management systems. AI technologies have been widely applied in retrieval systems. Exploiting knowledge more efficiently is a major research field. In addition, user oriented value added systems require intelligent processing and machine learning in many forms.

An important future trend for AI methods in IR will be the context specific adaptation of retrieval methods.

Machine learning can be applied to find optimized functions for collections or queries.

KEY TERMS

Adaptation: Adaptation is a process of modification based on input or observation. An information system should adapt itself to the specific needs of individual users in order to produce optimized results.

Indexing: Indexing means the assignment of terms (words) which represent a document in an index. Indexing can be carried out manually or automatically. Automatic indexing requires the elimination of stop-words and stemming.

Information Retrieval: Information retrieval is concerned with the representation and knowledge and subsequent search for relevant information within these knowledge sources. Information retrieval provides the technology behind search engines.

Link Analysis: The links between pages on the web are a large knowledge source which is exploited by link analysis algorithms for many ends. Many algorithms

similar to PageRank determine a quality or authority score based on the number of in-coming links of a page. Furthermore, link analysis is applied to identify thematically similar pages, web communities and other social structures.

Recommendation Systems: Actions or content is suggested to the user based on past experience collected from other users. Very often, documents are recommended based on similarity profiles between users.

Term Expansion: Terms not present in the original query to an information retrieval system entered by the user are added automatically. The expanded query is then sent to the system again.

Weighting: Weighting determines the importance of a term for a document. Weights are calculated using many different formulas which consider the frequency of each term in a document and in the collection as well as the length of the document and the average or maximum length of any document in the collection.

Artificial Intelligence in Computer–Aided Diagnosis

Paulo Eduardo Ambrósio
Santa Cruz State University, Brazil

INTRODUCTION

Professionals of the medical radiology area depend directly on the process of decision making in their daily activities. This process is mainly based on the analysis of a great amount of information obtained for the evaluation of radiographic images.

Some studies demonstrate the great capacity of Artificial Neural Networks (ANN) in support systems for diagnosis, mainly in applications as pattern classification.

The objective of this article is to present the development of an ANN-based system, verifying its behavior as a feature extraction and dimensionality reduction tool, for recognition and characterization of patterns, for posterior classification in normal and abnormal patterns.

BACKGROUND

The computer-aided diagnosis (CAD) is considered one of the main areas of research of the medical images and radiological diagnosis (Doi, 2005).

According to Giger (2002) “In the future, is probable that all the medical images have some form of executed CAD to benefit to the results and the patient cares”.

The diagnosis of the radiologist is normally based on qualitative interpretation of the analyzed data, that can be influenced and be harmed by many factors, as low quality of the image, visual fatigue, distraction, overlapping of structures, amongst others (Azevedo-Marques, 2001). Moreover, the human beings possess limitations in its visual ability, which can harm the analysis of a medical image, mainly in the detection of determined presented patterns (Giger, 2002).

Research demonstrates that when the analysis is carried out by two radiologists, the diagnosis sensitivity is significantly increases (Thurfjell *et al.*, 1994). In this direction, the CAD can be used as a second specialist,

when providing the computer reply as a second opinion (Doi, 2005).

Many works analyze the radiologist performance front the use of a CAD systems, of which we detach the research of Jiang *et al.* (2001) and Fenton *et al.* (2007).

In the development of CAD systems, techniques from two computational areas are normally used: Computer Vision and Artificial Intelligence.

From the area of Computer Vision, techniques of image processing for enhancement, segmentation and feature extraction are used (Azevedo-Marques, 2001).

The enhancement objectives to improve an image to make it more appropriate for a specific application (Gonzalez & Woods, 2001). In applications with digital medical images, the enhancement is important to facilitate the visual analysis on the part of the specialist.

The segmentation is the stage where the image is subdivided in parts or constituent objects (Gonzalez & Woods, 2001). The result of the segmentation is a set of objects that can be analyzed and quantified individually, representing determined characteristic of the original image.

The final stage involved in image processing is the feature extraction, that it basically involves the quantification of elements that compose segmented objects of the original image, such as size, contrast and form.

After concluded this first part, the quantified attributes are used for the classification of the structures identified in the image, normally using methods of Artificial Intelligence. According to Kononenko (2001), the use of Artificial Intelligence in the support to the diagnosis is efficient, for allowing a complex data analysis of simple and direct form.

Many methods and techniques of Artificial Intelligence can be applied in this stage, normally with the objective to identify and to separate the patterns in distinct groups (Theodorides & Koutroumbas, 2003), for example, normal and abnormal patterns. According to Kahn Jr (1994), among the main techniques, can be

cited: rule-based reasoning, artificial neural networks, bayesian networks, case-based reasoning. To these, the statistical methods, the genetic algorithms and the decision trees can be added.

A problem that reaches most of the applications of pattern recognition is the data dimensionality. The dimensionality is associated with the number of attributes that represent a pattern, that is, the dimension of the search space. When this space contains only the most relevant attributes, the classification process is faster and consumes little processing resources (Jain *et al.*, 2000), and also allows for greater precision of the classifier.

In the problems of medical image processing, the importance of the dimensionality reduction is accentuated; therefore normally the images to be processed are composed of a very great number of pixels, used as basic attributes in the classification.

The feature extraction is a common boarding to effect the dimensionality reduction. Of general form, an extraction algorithm creates a new set of attributes from transformations or combinations of the original set.

Some methods are studied with the intention to promote the feature extraction and, consequently, the dimensionality reduction, such as statistical methods, methods based on the signal theory, and artificial neural networks (Verikas & Bacauskiene, 2002).

As example of the use of artificial neural networks in the support to the medical diagnosis, we can cite the research of Papadopoulos *et al.* (2005) and André & Rangayan (2006).

MAIN FOCUS OF THE ARTICLE

In this paper, we also present a proposal of use of Artificial Intelligence in the stage of feature extraction, substituting the traditional techniques of image processing.

Traditionally, the feature extraction is carried out on the basis of statistical or spectral techniques, which result in, for example, texture or geometric attributes.

After these attributes are obtained, techniques of Artificial Intelligence are applied in the pattern classification.

Our proposal is the use of ANN also for feature extraction.

Feature Extraction with ANNs

The feature extraction with the use of Artificial Neural Networks functions basically as a selection of characteristics that represent the original data set.

This selection of characteristics is related to a process in which a data set is transformed into a space of characteristics that, in theory, accurately describes the same information as the original space of the data. However, the transformation is projected in such a way that the data set is represented by a reduced effective characteristic, keeping most of the intrinsic information to the data, that is, the original data set suffers a significant dimensionality reduction (Haykin, 1999).

The dimensionality reduction is extremely useful in applications that involve digital image processing, which normally depend on a very high number of data points to be manipulated.

In summary, the feature extraction with ANNs transforms the original set of pixels into a map, of reduced dimensions, that represents the original image without a significant loss of information.

For this function, self-organizing neural networks are normally used, as for example, the Kohonen's Self-Organizing Map (SOM).

The self-organizing map searches ways to transform one determined pattern into a bi-dimensional map, following a certain topological order (Haykin, 1999). The elements that compose the map are distributed in an only layer, having formed a grid (Figure 1).

Figure 1. Illustrative representation of a Kohonen's self-organizing map

All the elements of the grid receive the input signal of all variables, associated to its respective weights. The calculation of its value of exit is carried through by one determined function, on the basis of the weights of the connections, and it is used to identify the winning element.

Mathematically, each element of the grid is represented by a vector composed of the weights of connection, with the same dimension of the input space, that is, the amount of elements that compose the vector corresponds to the amount of input variables of the problem (Haykin, 1999).

Methodology

As application example, a self-organizing neural network for the feature extraction of images of chest radiographs was developed, objectifying the characterization of normal and abnormal patterns.

Each original image was divided in 12 parts, having as base the anatomical division normally used in the diagnosis of the radiologist. Each part is formed by approximately 250,000 pixels.

With the use of the proposal self-organizing network, a reduction for only 240 representative elements was obtained, with satisfactory results in the final pattern classification.

A detailed description of the methodology can be found in (Ambrósio, 2007; Azevedo-Marques *et al.*, 2007).

FUTURE TRENDS

The developed study shows the possibilities of application of the self-organizing networks in the feature extraction and dimensionality reduction; however, other types of neural networks can also be used for this purpose. New studies need to be carried out to compare the results and adequacy of the methodology.

CONCLUSION

The contribution of the Information Technology is undeniable as support tool to the medical decision making. The Artificial Intelligence presents itself as a great source of important techniques to be used in this direction.

It can be evidenced that the technique of artificial neural networks highlights its great versatility and robustness, providing sufficiently satisfactory results, when used and implemented well.

The use of an automatic system of image analysis can assist the radiologist, when used as a tool of 'second opinion', or second reading, in the analysis of possible inexact cases.

It is also observed that the use of the proposed methodology represents a significant profit in the image processing of chest radiographs, for its peculiar characteristics.

KEY TERMS

Computer-Aided Diagnosis: Research area that enclose the development of computational techniques and procedures for aid to the health professionals in process of decision making for the medical diagnosis.

Dimensionality Reduction: Finding a reduced data set, with the capacity of mapping a bigger set.

Feature Extraction: Finding of representative features of a determined problem from samples with different characteristics.

Medical Images: Images generated in special equipment, used for aid to the medical diagnosis. Ex.: X-Ray images, Computer Tomography, Magnetic Resonance Images.

Pattern Recognition: Research area that enclose the development of methods and automatized techniques for identification and classification of samples in specific groups, in accordance with representative characteristics.

Radiological Diagnosis: Medical diagnosis based in analysis and interpretation of patterns observed in medical images.

Self-Organizing Maps: Category of algorithms based on artificial neural networks that searches, by means of self-organization, to create a map of characteristics that represents the involved samples in a determined problem.

Artificial Neural Networks and Cognitive Modelling

Amanda J.C. Sharkey
University of Sheffield, UK

INTRODUCTION

In their heyday, artificial neural networks promised a radically new approach to cognitive modelling. The connectionist approach spawned a number of influential, and controversial, cognitive models. In this article, we consider the main characteristics of the approach, look at the factors leading to its enthusiastic adoption, and discuss the extent to which it differs from earlier computational models. Connectionist cognitive models have made a significant impact on the study of mind. However connectionism is no longer in its prime. Possible reasons for the diminution in its popularity will be identified, together with an attempt to identify its likely future.

The rise of connectionist models dates from the publication in 1986 by Rumelhart and McClelland, of an edited work containing a collection of connectionist models of cognition, each trained by exposure to samples of the required tasks. These volumes set the agenda for connectionist cognitive modellers and offered a methodology that subsequently became the standard. Connectionist cognitive models have since been produced in domains including memory retrieval and category formation, and (in language) phoneme recognition, word recognition, speech perception, acquired dyslexia, language acquisition, and (in vision) edge detection, object and shape recognition. More than twenty years later the impact of this work is still apparent.

BACKGROUND

Seidenberg and McClelland's (1989) model of word pronunciation is a well-known connectionist example. They used backpropagation to train a three-layer network to map an orthographic representation of words and non-words onto a distributed phonological representation, and an orthographic output representation. The model is claimed to provide a good fit to

experimental data from human subjects. Humans can make rapid decisions about whether a string of letters is a word or not, (in a lexical decision task), and can readily pronounce both words and non-words. The time they take to do both is affected by a number of factors, including the frequency with which words occur in language, and the regularity of their spelling. The trained artificial neural network outputs both a phonological and an orthographic representation of its input. The phonological representation is taken as the equivalent to pronouncing the word or non-word. The orthographic representation, and the extent to which it duplicates the original input, is taken to be the equivalent of the lexical decision task.

The past tense model (McClelland & Rumelhart, 1986) has also been very influential. The model mirrors several aspects of human learning of verb endings. It was trained on examples of the root form of the word as input, and of the past-tense form as output. Each input and output was represented as a set of context-sensitive phonological features, coded and decoded by means of a fixed encoder/decoder network. A goal of the model was to simulate the stage-like sequences of past tense learning shown by humans. Young children first correctly learn the past tense of a few verbs, both regular (e.g. looked) and irregular (e.g. went, or came). In stage 2 they often behave as though they have inferred a general rule for creating the past tense, (adding -ed to the verb stem). But they often over-generalise this rule, and add -ed to irregular verbs (e.g. comed). There is a gradual transition to the final stage in which they learn to produce the correct past tense form of both regular and exception words. Thus their performance exhibits a U-shaped function for irregular verbs (initially correct, then often wrong, then correct again).

The model was trained in stages on 506 English verbs. First, it was trained on 10 high frequency verbs (regular, and irregular). Then medium frequency verbs (mostly regular) were introduced and trained for a number of epochs. A dip in performance on the irregular verbs occurred shortly after the introduction

of the medium frequency verbs – a dip followed by a gradual improvement that resembled the U-shaped curve found in human performance.

THE STRENGTHS AND LIMITATIONS OF CONNECTIONIST COGNITIVE MODELLING

The models outlined above exhibit five typical features of connectionist models of cognition: (i) They provide an account that is related to and inspired by the operations of the brain; (ii) They can be used both to model mental processes, and to simulate the actual behaviour involved; (iii) They can provide a ‘good fit’ to the data from psychology experiments; (iv) The model, and its fit to the data, is achieved without explicit programming and (v) They often provide new accounts of the data. We discuss these features in turn.

First there is the idea that a connectionist cognitive model is inspired by, and related to, the way in which brains work. Connectionism is based on both the alleged operation of the nervous system and on distributed computation. Neuron-like units are connected by means of weighted links, in a manner that resembles the synaptic connections between neurons in the brain. These weighted links capture the knowledge of the system; they may be arrived at either analytically or by “training” the system with repeated presentations of input-output training examples. Much of the interest in connectionist models of cognition was that they offered a new account of the way in which knowledge was represented in the brain. For instance, the behaviour of the past tense learning model can be described in terms of rule following – but its underlying mechanism does not contain any explicit rules. Knowledge about the formation of the past tense is distributed across the weights in the network.

Interest in brain-like computing was fuelled by a growing dissatisfaction with the classical symbolic processing approach to modelling mind and its relationship to the brain. Even though theories of symbol manipulation could account for many aspects of human cognition, there was concern about how such symbols might be learnt and represented in the brain. Functionalism (Putnam, 1975) explicitly insisted that details about how intelligence and reasoning were actually implemented were irrelevant. Concern about the

manipulation of meaningless, ungrounded symbols is exemplified by Searle’s Chinese Room thought-experiment (1980). Connectionism, by contrast, offered an approach that was based on learning, made little use of symbols, and was related to the way in which the brain worked. Arguably, one of the main contributions that connectionism has made to the study and understanding of mind has been the development of a shared vocabulary between those interested in cognition, and those interested in studying the brain.

The second and third features relate to the way in which artificial neural nets can both provide a model of a cognitive process and simulate a task, and provide a good fit to the empirical data. In Cognitive Psychology, the emphasis had been on building models that could account for the empirical results from human subjects, but which did not incorporate simulations of experimental tasks. Alternatively, in Artificial Intelligence, models were developed that performed tasks in ways that resembled human behaviour, but which took little account of detailed psychological evidence. However, as in the two models described here, connectionist models both simulated the performance of the human tasks, and were able to fit the data from psychological investigations.

The fourth feature is that of achieving the model and the fit to the data without explicit handwiring. It can be favourably contrasted to the symbolic programming methodology of Artificial Intelligence, where the model is programmed step by step, leaving room for ad hoc modifications and kludges. The fifth characteristic is the possibility of providing a novel explanation of the data. In their model of word pronunciation, Seidenberg and McClelland showed that their artificial neural network provided an integrated (single mechanism) account of data on both regular and exception words where previously the old cognitive modelling conventions had forced an explanation in terms of a dual route. Similarly, the past-tense model was formulated as a challenge to rule-based accounts: although children’s performance can be described in terms of rules, it was claimed that the model showed that the same behaviour could be accounted for by means of an underlying mechanism that does not use explicit rules.

In its glory days, connectionism’s claims about novel explanations of stimulated much debate. There was also much discussion of the extent to which connectionism could provide an adequate account of higher mental processes. Fodor and Pylyshyn (1988)

mounted an attack on the representational adequacy of connectionism. Connectionists retaliated, and in papers such as van Gelder's (1990) the argument was made that not only could they provide an account of the structure sensitive processes underlying human language, but that connectionism did so in a novel manner: the *eliminative connectionist* position.

Now the dust has subsided, connectionist models do not seem as radically different to other modelling approaches as was once supposed. It was held that one of their strengths was their ability to model mental processes, simulate behaviour, and provide a good fit to data from psychology experiments *without being explicitly programmed to do so*. However, there is now greater awareness that decisions about factors such as the architecture of the net, the form its representations will take, and even the interpretation of its input and output, are tantamount to a form of *indirect, or extensional programming*.

Controlling the content, and presentation of the training sample, is an important aspect of extensional programming. When Pinker and Prince (1988) criticised the past tense model, an important element of their criticisms was that the experimenters had unrealistically tailored the environment to produce the required results, and that the results were an artifact of the training data. Although the results indicated a U-shaped curve in the rate of acquisition, as occurs with children, Pinker and Prince argued that this curve occurred only because the net was exposed to the verbs in an unrealistically structured order. Further research has largely answered these criticisms, but it remains the case that selection of the input, and control of the way that it is presented to the net, affects what the net learns. A similar argument can be made about the selection of input representations.

In summary: there has been debate about the novelty of connectionism, and its ability to account for higher level cognitive processing. There is however general acknowledgement that the approach made a lasting contribution by indicating how cognitive processes could be implemented at the level of neurons. Despite this, the connectionist approach to cognitive modelling is no longer as popular as it once was. Possible reasons are considered below:

- **Difficult challenges:** A possible reason for the diminished popularity of artificial neural nets is that as Elman (2005) suggests, “we have arrived

at the point where the easy targets have been identified but the tougher problems remain”. Difficult challenges to be met include the idea of scaling up models to account for wider ranges of phenomena, and building models that can account for more than one behaviour.

- **Greater understanding:** As a result of our greater understanding of the operation and inherent limitations of artificial neural nets, some of their attraction has faded with their mystery. They have become part of the arsenal of statistical methods for pattern recognition, and much recent research on artificial neural networks has focused more on questions about whether the best level of generalisation has been efficiently achieved, than on modelling cognition.

Also there is greater knowledge of the limitations of artificial neural nets, such as the problem of the “catastrophic interference” associated with backpropagation. Backpropagation performs impressively when all of the training data are presented to the net on each training cycle, but its results are less impressive when such training is carried out sequentially and a net is fully trained on one set of items before being trained on a new set. The newly learned information often interferes with, and overwrites, previously learned information. For instance, McCloskey and Cohen (1989) used backpropagation to train a net on the arithmetic problem of + 1 addition (e.g. 1+1, 2+1, ..., 9+1). They found that when they proceeded to train the same net to add 2 to a given number, it “forgot” how to add 1. Sequential training of this form results in catastrophic interference. Sharkey and Sharkey (1995) demonstrated that it is possible to avoid the problem if the training set is sufficiently representative of the underlying function, or there are enough sequential training sets. In terms of this example, if the function to be learned is both + 1 and + 2, then training sets that incorporate enough examples of each could lead to the net learning to add either 1 or 2 to a given number. However, this is at the expense of being able to discriminate between those items that have been learned from those that have not.

This example is related to another limitation of artificial neural nets: their inability to extrapolate beyond their training set. Although humans can readily grasp the idea of adding one to any given number, it is not so straightforward to train the net to extrapolate beyond the data on which it is trained. It has been argued

(Marcus, 1998) that this inability of artificial neural nets trained using backpropagation to generalise beyond their training space provides a major limitation to the power of connectionist nets: an important one, since humans can readily generalise universal relationships to unfamiliar instances. Clearly there are certain aspects of cognition, particularly those to do with higher level human abilities, such as their reasoning and planning abilities, that are more difficult to capture within connectionist models.

- **Changing zeitgeist:** There is now an increased interest in more detailed modelling of brain function, and a concomitant dissatisfaction with the simplicity of cognitive models that often consisted of “a small number of neurons connected in three rows” (Hawkins, 2004). Similarly, there is greater impatience with the emphasis in connectionism on the biologically implausible backpropagation learning algorithm. At the same time, there is greater awareness of the role the body plays in cognition, and the relationships between the body, the brain, and the environment (e.g. Clark, 1999). Traditional connectionist models do not fit easily with the new emphasis on embodied cognition (e.g. Pfeifer and Scheier, 1999).

FUTURE TRENDS

One expected future trend will be to focus on the difficult challenges. It is likely that investigations will explore how models of isolated processes, such as learning the past tense of verbs, might fit into more general accounts of language learning, and of cognition. There are further questions to be addressed about the developmental origin of many aspects of cognition, and the origin and progression of developmental disorders.

Connectionist cognitive modelling is likely to change in response to the new zeitgeist. A likely scenario is that artificial neural nets will continue to be used for cognitive modeling, but not exclusively as they were before. They will continue to form part of hybrid approaches to cognition (Sun, 2003), in combination with symbolic methods. Similarly, artificial neural nets can be used in combination with evolutionary algorithms to form the basis of adaptive responses to the environment. Rather than training artificial neural nets, they can be adapted by means of evolutionary methods, and

used as the basis for robotic controllers (e.g. Nolfi and Floreano, 2000). Such changes will ensure a future for connectionist modeling, and stimulate a new set of questions about the emergence of cognition in response to an organism’s interaction with the environment.

CONCLUSION

In this article we have described two landmark connectionist cognitive models, and considered their characteristic features. We outlined the debates over the novelty and sufficiency of connectionism for modelling cognition, and argued that in some respects the approach shares features with the modelling approaches that preceded it. Reasons for a gradual waning of interest in connectionism were identified, and possible futures were discussed. Connectionism has had a strong impact on cognitive modelling, and although its relationship to the brain is no longer seen as a strong one, it provided an indication of the way in which cognitive processes could be accounted for in the brain. It is argued here that although the approach is no longer ubiquitous, it will continue to form an important component of future cognitive models, as they take account of the interactions between thought, brains and the environment.

KEY TERMS

Chinese Room: In Searle's thought experiment, he asks us to imagine a man sitting in a room with a number of rule books. A set of symbols is passed into the room. The man processes the symbols according to the rule books, and passes a new set of symbols out of the room. The symbols posted into the room correspond to a Chinese question, and the symbols he passes out are the answer to the question, in Chinese. However, the man following the rules has no knowledge of Chinese. The example suggests a computer program could similarly follow rules in order to answer a question without any understanding.

Classical Symbol Processing: The classical view of cognition was that it was analogous to symbolic computation in digital computers. Information is represented as strings of symbols, and cognitive processing involves the manipulation of these strings by means of a set of rules. Under this view, the details of how such computation is implemented are not considered important.

Connectionism: Connectionism is the term used to describe the application of artificial neural networks to the study of mind. In connectionist accounts, knowledge is represented in the strength of connections between a set of artificial neurons.

Eliminative Connectionism: The eliminative connectionist is concerned to provide an account of cognition that eschews symbols, and operates at the subsymbolic level. For instance, the concept of "dog" could be captured in a distributed representation as a number of input features (e.g. four-footed, furry, barks etc) and would then exist in the net in the form of the weighted links between its neuron like units.

Generalisation: Artificial neural networks, once trained, are able to generalise beyond the items on which they were trained and to produce a similar output in response to inputs that are similar to those encountered in training

Implementational Connectionism: In this less extreme version of connectionism, the goal is to find

a means of implementing classical symbol processing using artificial networks – and to find a way of accounting for symbol processing at the level of neurons.

Lexical Decision: Lexical decision tasks are a measure devised to look at the processes involved in word recognition. A word or pseudoword (a meaningless string of letters, conforming to spelling rules) is presented, and the reader is asked to press a button to indicate whether the display was a word or not. The time taken to make the decision is recorded in milliseconds. The measure can provide an indication of various aspects of word processing – for instance how familiar the word is to the reader.

Artificial NeuroGlial Networks

INTRODUCTION

More than 50 years ago **connectionist systems (CSs)** were created with the purpose to process information in the computers like the human brain (McCulloch & Pitts, 1943). Since that time these systems have advanced considerably and nowadays they allow us to resolve complex problems in many disciplines (classification, clustering, regression, etc.). But this advance is not enough. There are still a lot of limitations when these systems are used (Dorado, 1999). Mostly the improvements were obtained following two different ways. Many researchers have preferred the construction of **artificial neural networks (ANNs)** based in mathematic models with diverse equations which lead its functioning (Cortes & Vapnik, 1995; Haykin, 1999). Otherwise other researchers have pretended the most possibly to make alike these systems to human brain (Rabúñal, 1999; Porto, 2004).

The systems included in this article have emerged following the second way of investigation. **CSs** which pretend to imitate the neuroglial nets of the brain are introduced. These systems are named **Artificial NeuroGlial Networks (ANGNs)** (Porto, 2004). These **CSs** are not only made of neuron, but also from elements which imitate glial neurons named **astrocytes** (Araque, 1999). These systems, which have hybrid training, have demonstrated efficacy when resolving classification problems with totally connected feed-forward multi-layer networks, without backpropagation and lateral connections.

BACKGROUND

The **ANNs** or **CSs** emulate the biological neural networks in that they do not require the programming of tasks but generalise and learn from experience. Current **ANNs** are composed by a set of very simple processing elements (**PEs**) that emulate the biological neurons and by a certain number of connections between them.

Until now, researchers that pretend to emulate the brain, have tried to represent in **ANNs** the importance the neurons have in the Nervous System (**NS**). However, during the last decades research has advanced remarkably in the Neuroscience field, and increasingly complex neural circuits, as well as the Glial System (**GS**), are being observed closely. The importance of the functions of the **GS** leads researchers to think that their participation in the processing of information in the **NS** is much more relevant than previously assumed. In that case, it may be useful to integrate into the artificial models other elements that are not neurons.

Since the late 80s, the application of innovative and carefully developed cellular and physiological techniques (such as patch-clamp, fluorescent ion-sensible images, confocal microscopy and molecular biology) to glial studies has defied the classic idea that **astrocytes** merely provide a structural and trophic support to neurons and suggests that these elements play more active roles in the physiology of the Central Nervous System.

New discoveries are now unveiling that the glia is intimately linked to the active control of neural activity and takes part in the regulation of synaptic neurotransmission (Perea & Araque, 2007). Abundant evidence has suggested the existence of bidirectional communication between astrocytes and neurons, and the important active role of the astrocytes in the **NS's**

physiology (Araque et al., 2001; Perea & Araque, 2005). This evidence has led to the proposal of a new concept in synaptic physiology, the tripartite synapse, which consists of three functional elements: the presynaptic and postsynaptic elements and the surrounding astrocytes (Araque et al., 1999). The communication between these three elements has highly complex characteristics, which seem to reflect more reliably the complexity of the **information processing** between the elements of the NS (Martin & Araque, 2005).

So there is no question about the existence of communication between astrocytes and neurons (Perea & Araque, 2002). In order to understand the motives of this reciprocated signalling, we must know the differences and similarities that exist between their properties. Only a decade ago, it would have been absurd to suggest that these two cell types have very similar functions; now we realise that the similarities are striking from the perspective of chemical signalling. Both cell types receive chemical inputs that have an impact on the ionotropic and metabotropic receptors. Following this integration, both cell types send signals to their neighbours through the release of chemical transmitters. Both the neuron-to-neuron signalling and the neuron-to-astrocyte signalling show plastic properties that depend on the activity (Pasti et al., 1997). The main difference between **astrocytes** and neurons is that many neurons extend their axons over large distances and conduct action potentials of short duration at high speed, whereas the **astrocytes** do not exhibit any electric excitability but conduct calcium spikes of long duration (tens of seconds) over short distances and at low speed. The fast signalling, and the input/output functions in the central NS that require speed, seem to belong to the neural domain. But what happens with slower events, such as the induction of memories, and other abstract processes such as thought processes? Does the signalling between astrocytes contribute to their control? As long as there is no answer to these questions, research must continue; the present work offers new ways to advance through the use of Artificial Intelligence (AI) techniques.

Therefore not only it is pretended to improve the **CSs** incorporating elements imitating astrocytes, but it is also intended to benefit Neuroscience with the study of brain circuits since other point of view, the AI.

The most recent works in this area are presented by Porto et al (Porto et al., 2007; Porto et al., 2005; Porto, 2004).

MAIN FOCUS OF THE ARTICLE

All the design possibilities, for the architecture as well as for the training process of an ANN, are basically oriented towards minimising the error level or reducing the system's learning time. As such, it is in the optimisation process of a mechanism, in case the ANN, that we must find the solution for the many parameters of the elements and the connections between them.

Considering possible future improvements that optimize an ANN with respect to minimal error and minimal training time, our models will be the brain circuits, in which the participation of elements of the GS is crucial to process the information. In order to design the integration of these elements into the ANN and elaborate a learning method for the resulting ANG that allows us to check whether there is an improvement in these systems, we have analysed the main existing training methods that will be used for the elaboration. We have analysed Non-Supervised and Supervised Training methods, and other methods that use or combine some of their characteristics and complete the analysis: Training by Reinforcement, Hybrid Training and Evolutionary Training.

Observed Limitations

Several experiments with ANNs have shown the existence of conflicts between the functioning of the CS and biological neuron networks, due to the use of methods that did not reflect reality. For instance, in the case of a multilayer perceptron, which is a simple CS, the synaptic connections between the PEs have weights that can be excitatory or inhibitory, whereas in the natural NS, are the neurons that seem to represent these functions, not the connections; recent research (Perea & Araque, 2007) indicates that the cells of the GS, more concretely the astrocytes, also play an important role.

Another limitation concerns the learning algorithm known as "Backpropagation", which implies that the change of the connections value requires the backwards transmission of the error signal in the ANN. It was traditionally assumed that this behaviour was impossible in a natural neuron, which, according to the "dynamic polarisation" theory of Ramón y Cajal (1911), is unable to efficiently transmit information inversely through the axon until reaching the cellular soma; new research however has discovered that neurons can send information to presynaptic neurons

under certain conditions, either by means of existing mechanisms in the dendrites or else through various interventions of glial cells such as astrocytes.

If the learning is supervised, it implies the existence of an “instructor”, which in the context of the brain means a set of neurons that behave differently from the rest in order to guide the process. At present, the existence of this type of neurons is biologically indemonstrable, but the GS seems to be strongly implied in this orientation and may be the element that configures an instructor that until now had not been considered.

It is in this context that the present study analyses to what extent the latest discoveries in Neuroscience (Araque et al., 2001; Perea & Araque, 2002) contribute to these networks: discoveries that proceed from cerebral activity in areas that are believed to be involved in the learning and processing of information (Porto et al., 2007).

Artificial Neuroglial Networks

Many researchers have used the current potential of computers and the efficiency of computational models to elaborate “biological” computational models and reach a better understanding of the structure and behaviour of both pyramidal neurons, which are believed to be involved in learning and memory processes (LeRay et al., 2004; Fernández et al., 2007), and astrocytes (Porto, 2004; Perea & Araque, 2002). These models have provided a better understanding of the causes and factors that are involved in the specific functioning of biological circuits. The present work will use these new insights to progress in the field of Computer Sciences and more concretely in AI.

Figure 1. Artificial NeuroGlial network scheme

We present ANGns (figure 1) that include both artificial neurons and processing control elements that represent the astrocytes, and whose functioning follows the steps that were successfully applied in the construction and use of CS: design, training, testing and execution.

Also, since the computational studies of the learning with ANNs are beginning to converge towards evolutionary computation methods (Dorado, 1999), we will combine the optimisation in the modification of the weights (according to the results of the biological models) with the use of Genetic Algorithms (GAs) in order to find the best solution for a given problem. This evolutionary technique was found to be very efficient in the training phase of the CS (Rabuañal, 1998), because it helps to adapt the CS to the optimal solution according to the inputs that enter the system and the outputs that must be produced by the system. This adaptation phenomenon takes place in the brain thanks to the plasticity of its elements and may be partly controlled by the GS; it is for this reason that we consider the GA as a part of the “artificial glia”. The result of this combination is a hybrid learning method (Porto, 2004).

The design of the ANGns is oriented towards classification problems that are solved by means of simple networks, i.e. multilayer networks, although future research may lead to the design of models in more complex networks. It seems a logical approach to start the design of these new models with simple ANNs, and to orientate the latest discoveries on **astrocytes** and pyramidal neurons in information processing towards their use in classification networks, since the control of the reinforcement or weakening of the connections in the brain is related to the adaptation or plasticity of the connections, which lead to the generation of activation ways. This process can therefore improve the classification of the patterns and their recognition by the ANGn.

A detailed description of the functioning of the ANGns and results with these systems can be found in Porto et al (Porto, 2004; Porto et al., 2005; Porto et al., 2007).

FUTURE TRENDS

We keep on analysing other synaptic modification possibilities based on brain behaviour to apply them

to new CSs which can solve simple problems with simple architectures.

Moreover, given that it has been proved that the glia acts upon complex brain circuits, and that the more an individual's brain has developed, the more glia he has in his nervous system (following what Cajal said one hundred years ago (Ramón y Cajal, 1911)), we are applying the observed brain behaviour to more complex network architectures. Particularly after having checked that a more complex network architecture achieved better results in the problem presented here.

For the same reason, we intend to analyse how the new CSs solve complex problems, for instance time processing ones where totally or partially recurrent networks would play a role. These networks could combine their functioning with this new behaviour.

CONCLUSION

This article presents CSs composed by artificial neurons and artificial glial cells. The design of artificial models did not aim at obtaining a perfect copy of the natural model but a series of behaviours whose final functioning is approached to it as much as possible. Nevertheless, a close similarity between both is indispensable to improve the output, and may result in more "intelligent" behaviours.

The synaptic modifications introduced in the CSs, and based on the modelled brain processes enhance the training of multilayer architectures.

We must remember that the innovation of the existing ANNs models towards the development of new architectures is conditioned by the need to integrate the new parameters into the learning algorithms so that they can adjust their values. New parameters, that provide the process element models of the ANNs with new functionalities, are harder to come by than optimizations of the most frequently used algorithms that increase the calculations and basically work on the computational side of the algorithm. The ANGNS integrate new elements and thanks to a hybrid method this approach did not complicate the training process.

The research with these ANGNS benefits AI because it can improve **information processing** capabilities which would allow us to deal with a wider range of problems. Moreover, this has indirectly benefited Neuroscience since experiments with computational models that simulate brain circuits pave the way for

difficult experiments carried out in laboratories, as well as providing new ideas for research.

KEY TERMS

Artificial Neural Network: A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Astrocytes: Astrocytes are a sub-type of the glial cells in the brain. They perform many functions, including the formation of the blood-brain barrier, the provision of nutrients to the nervous tissue, and play a principal role in the repair and scarring process in the brain. They modulate the synaptic transmission and

recently their crucial role in the information processing was discovered.

Backpropagation Algorithm: A supervised learning technique used for training ANNs, based on minimising the error obtained from the comparison between the outputs that the network gives after the application of a set of network inputs and the outputs it should give (the desired outputs).

Evolutionary Computation: Solution approach guided by biological evolution, which begins with potential solution models, then iteratively applies algorithms to find the fittest models from the set to serve as inputs to the next iteration, ultimately leading to a model that best represents the data.

Genetic Algorithms: Genetic algorithms (GAs) are adaptive heuristic search algorithm premised on the evolutionary ideas of natural selection and genetic. The basic concept of GAs is designed to simulate processes in natural system necessary for evolution, specifically those that follow the principles first laid down by Charles Darwin of survival of the fittest. As such they represent an intelligent exploitation of a random search within a defined search space to solve a problem.

Glial Sytem: Commonly called glia (greek for “glue”), are non-neuronal cells that provide support and nutrition, maintain homeostasis, form myelin, and participate in signal transmission in the nervous system. In the human brain, glia cells are estimated to outnumber neurons by about 10 to 1.

Hybrid Training: Learning method that combines the supervised and unsupervised training of Connectionist Systems.

Synapse: Specialized junctions through which the cells of the nervous system signal to each other and to non-neuronal cells such as those in muscles or glands.

Association Rule Mining

Vasudha Bhatnagar

University of Delhi, India

INTRODUCTION

Data mining is a field encompassing study of the tools and techniques to assist humans in intelligently analyzing (mining) mountains of data. Data mining has found successful applications in many fields including sales and marketing, financial crime identification, portfolio management, medical diagnosis, manufacturing process management and health care improvement etc..

Data mining techniques can be classified as either descriptive or predictive techniques. Descriptive techniques summarize / characterize general properties of data, while predictive techniques construct a model from the historical data and use it to predict some characteristics of the future data. Association rule mining, sequence analysis and clustering are key descriptive data mining techniques, while classification and regression are predictive techniques.

The objective of this article is to introduce the problem of association rule mining and describe some approaches to solve the problem.

BACKGROUND

Association rule mining, one of the fundamental techniques of data mining, aims to extract interesting correlations, frequent patterns or causal structures among sets of items in data.

An association rule is of the form $X \rightarrow Y$ and indicates that the presence of items in the antecedent of rule (X) implies the presence of items in the consequent of rule (Y). For example, the rule $\{PC, Color Printer\} \rightarrow \{computer table\}$ implies that people who purchase a PC (personal computer) and a color printer also tend to purchase a computer table. These associations, however, are not based on the inherent characteristics of a domain (as in a functional dependency) but on the co-occurrence of data items in the dataset. Thus, association rule mining is a totally data driven technique.

Association rules have been successfully employed in numerous applications, some of which are listed below:

1. **Retail market analysis:** Discovery of association rules in retail data has been applied in departmental stores for floor planning, stock planning, focused marketing campaigns for product awareness, product promotion and customer retention.
2. **Web association analysis:** Association rules in web usage mining have been used to recommend related pages, discover web pages with common references, web pages with majority of same links (mirrors) and predictive caching. The knowledge is applied to improve web site design and speed up searches.
3. **Discovery of linked concepts:** Words or sentences that appear frequently together in documents are called linked concepts. Association rules can be used to discover linked concepts which further lead to the discovery of plagiarized text and the development of ontologies etc..

The problem of association rule mining (ARM) was introduced by Agrawal et al. (1993). Large databases of retail transactions called the market basket databases, which accumulate in departmental stores provided the motivation of ARM. The basket corresponds to a physical retail transaction in a departmental store and consists of the set of items a customer buys. These transactions are recorded in a database called the transaction database. The goal is to analyze the buying habits of customers by finding associations between the different items that customers place in their “shopping baskets”. The discovered association rules can also be used by management to increase the effectiveness of

Figure 1. Boolean database and corresponding transaction database

| TID | A | B | C | D | E |
|-----|---|---|---|---|---|
| 10 | 1 | 1 | 1 | 0 | 0 |
| 20 | 1 | 0 | 1 | 0 | 0 |
| 30 | 1 | 0 | 1 | 1 | 0 |
| 40 | 0 | 1 | 1 | 0 | 1 |
| 50 | 1 | 0 | 1 | 0 | 1 |

→

| TID | Items |
|-----|---------|
| 10 | A, B, C |
| 20 | A, C |
| 30 | A, C, D |
| 40 | B, C, E |
| 50 | A, C, E |

advertising, marketing, inventory management and reduce the associated costs.

The authors in (Agrawal et al., 1993) worked on a *boolean database* of transactions. Each record corresponds to a customer basket and contains transaction identifier (*TID*), transaction details and a *list of items* bought in the transaction. The list of items is represented by a boolean vector with a *one* denoting presence of corresponding item in the transaction and *zero* marking the absence. Figure 1 shows the *boolean database* of five transactions and the corresponding transaction database.

The problem of finding association rules is to find the columns with frequently co-occurring ones in the boolean database. However, most of the algorithms for ARM use the form of transaction database shown on the right. We give the mathematical formulation of the problem below.

MATHEMATICAL FORMULATION OF THE ARM PROBLEM

Let $I = \{i_1, i_2, \dots, i_n\}$ denote a set of items and D designate a database of N transactions. A transaction $T \in D$ is a subset of I i.e. $T \subseteq I$ and is associated with a unique identifier *TID*.

An *itemset* is a collection of one or more items. X is an itemset if $X \subseteq I$. A transaction is said to contain an itemset X if $X \subseteq T$. A *k-itemset* is an itemset that contains k items.

An *association rule* is of the form $X \rightarrow Y$ [*Support*, *Confidence*] where $X \subset I$, $Y \subset I$, $X \cap Y = \emptyset$, and *Support* and *Confidence* are rule evaluation metrics.

Support of an itemset X is the fraction of transactions that contain X . It denotes the probability that a transaction contains X .

$$\text{Support}(X) = P(X) =$$

$$\frac{\text{No. of transactions containing } X}{\text{Total number of transactions in } D}$$

Support of a rule $X \rightarrow Y$ in D is 's' if s% of transactions in D contain $X \cup Y$, and is computed as:

$$\text{Support}(X \rightarrow Y) = P(X \cup Y) =$$

$$\frac{\text{No. of transactions containin } X \cup Y}{\text{Total number of transactions in } D}$$

Support indicates the extent of prevalence of a rule. A rule with low support value represents a rare event.

Confidence of a rule measures its strength and provides an indication of the reliability of prediction made by the rule. A rule $X \rightarrow Y$ has a confidence 'c' in D if c% of transactions in D that contain X also contain Y . It is computed as the conditional probability that Y occurs in a transaction, given X is present in the same transaction, i.e.

$$\text{Confidence}(X \rightarrow Y) = P(Y/X) =$$

$$\frac{P(X \cup Y)}{P(X)}$$

Example 1: Consider the example database shown in Figure 2 (a). Here, $I = \{A, B, C, D, E\}$. Figures 2 (b) and 2 (c) show the computation of support and confidence for a rule.

Figure 2(a). Example of database transactions

| TID | Items |
|-----|---------|
| 10 | A, B,C |
| 20 | A, C |
| 30 | A, C, D |
| 40 | B, C, E |
| 50 | A, C, E |

Figure 2(b). Itemsets of size one and two

Figure 2(c). Computation of support and confidence

| |
|-------------------------------|
| Sup(A): 4 (80%), |
| Sup(C): 5 (100%) |
| Sup (AB): 1 (20%) |
| Sup(AC): 4 (80%), |
| Sup (ABC): 1 (20%), |
| Sup (ABCD): 0 (0%) |
| Sup(ABCDE): 0 (0%) |
| Confidence (A→C) = 4/4 (100%) |
| Confidence (C→A) = 4/5 (80%) |

With n items in I , the total number of possible association rules is very large ($O(3^n)$). However, the majority of these rules (associations) existing in D are not interesting for the user. Interestingness measures are employed to reduce the number of rules discovered by the algorithms. Foremost criterion of interestingness is the high prevalence of both the item-sets and rules, which is specified by the user as minimum support value. An itemset (rule) whose support is greater than or equal to a user specified minimum support (*minsup*) threshold is called a *Frequent Itemset (rule)*.

The second criterion of interestingness is the strength of the rule. A rule which has confidence greater than the user specified minimum confidence threshold (*minconf*) is interesting to the user.

Confidence, however, can sometimes be misleading. For instance, the confidence of a rule can be high even if antecedent and consequent of the rule are independent. *Lift* (also called *Interest*) and *Conviction* of a rule are other commonly used measures for rule interestingness (Dunham, 2002). A suitable measure of rule strength needs to be identified for an application.

MINING OF ASSOCIATION RULES

Since an association rule is an implication among itemsets, the brute-force approach to association rule generation requires examining relationships between all possible item-sets. Such a process would typically involve counting the co-occurrence of all itemsets in D and subsequently generating rules from them.

For n items, there are 2^n possible itemsets that need to be counted. This may require not only prohibitive amount of memory, but also complex indexing of counters. Since the user is interested only in frequent rules, one needs to count only the frequent itemsets before generating association rules. Thus, the problem of mining association rules is decomposed into two phases:

Phase I: Discovery of frequent itemsets

Phase II: Generation of rules from the frequent itemsets discovered in phase I.

Various algorithms for ARM differ in their approaches to optimize the time and storage requirement for counting in the first phase. Despite reducing the search space by imposing *minsup* constraint, frequent itemset generation is still a computationally expensive process. The *Anti-monotone property* of support is an important tool to further reduce the search space and is used in most association rule algorithms (Agrawal et al., 1994). According to this property, support of an itemset never exceeds the support of any of its subsets i.e. if X is an itemset, then for each of its subsets Y , $\text{sup}(X) \leq \text{sup}(Y)$. This property makes the set of frequent itemsets *downward closed*. The task of rule

Figure 3. Generation of association rules from frequent itemsets (Adapted from Dunham, 2002)

```

Algorithm: Gen-Rules
Input: F – Set of frequent itemsets
      minconf – Minimum confidence threshold
Output: R – set of strong association rules
Process:
  R = ∅
  For each f ∈ F do
    For each x ⊂ f such that x ≠ ∅ do
      If sup(f)/sup(x) ≥ minconf
        R = R ∪ {x → (f - x)}

```

generation is trivial once the set of frequent itemsets has been discovered.

Apriori algorithm uses a level-wise approach for discovering frequent itemsets (Agrawal et al., 1994). This algorithm makes multiple scans of the data. In each scan the algorithm generates and counts potential frequent itemsets (*candidates*). Candidate itemsets of size $k+1$ are generated by joining the frequent itemsets of size k , and are pruned exploiting the anti-monotonic property. At the end of the scan the set of frequent itemsets is confirmed. The strategy incurs massive I/O costs and has motivated a number of variants which reduce the number of counters (*candidates*) and the scans (Brin et al., 1997; Lin et al., 1998). The FP-growth algorithm (Han et al., 2000) uses a pattern growth method to avoid the costly process of candidate generation and testing, and therefore is considered as a major milestone. The algorithm uses an in-memory, tree based data structure called FP-Tree to store the database in a compressed form. Two passes are made over the database to construct the prefix tree, which is then used to generate frequent patterns. Lattice based approaches have also been proposed for efficient discovery of frequent itemsets (Zaki et al., 1998).

The task of generating rules (Phase II) from a given frequent itemsets is rather straight forward (Figure 3). It boils down to enumerating all subsets of a frequent itemset and finding the ratio of support of each itemset w.r.t. the support of each of its subsets. The subsets, whose ratio is more than the *minconf*, qualify as strong rules and are reported to the user.

TYPES OF ASSOCIATION RULES

Popularity of ARM has led to its application on many types of data and application domains. Some specialized kinds of association rules have been reported in data mining literature (Han & Kamber 2006). We describe here some of the important types:

1. **Quantitative Association Rules:** Quantitative association rules introduced the notion of mining associations between numeric attributes in addition to the categorical ones (Srikant et al., 1996). The quantitative association rules can be derived by either mapping the attribute values to a set of consecutive integers or partitioning them into intervals. Example of a quantitative association rule:

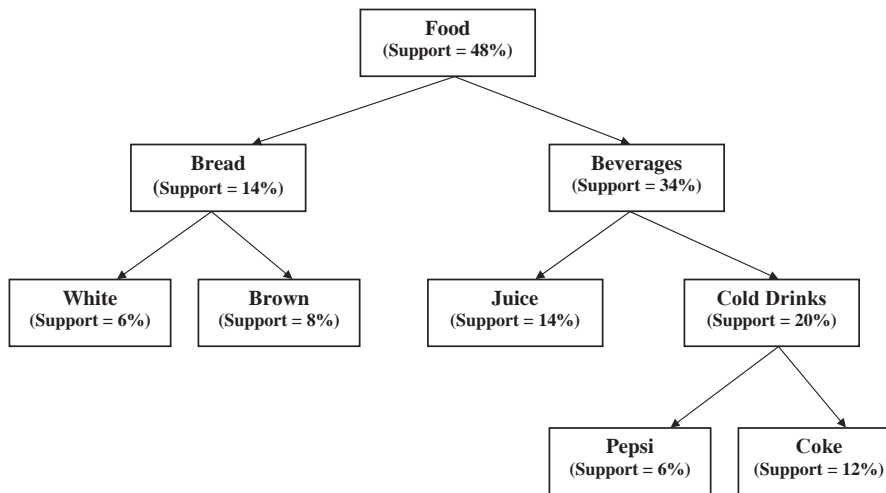

Age (x, “30...39”) ^ salary (x, “42...48K”) → buys(x, “car”) [1%, 75%]

2. **Multilevel Association Rules:** Many applications have an inherent *taxonomy* (*concept hierarchy*) among items (Figure 4). In such scenarios, association rules can be generated at different levels of the taxonomy, to capture knowledge at different levels of abstraction. As we move down the hierarchy (from generalized towards specialized values), the support of rules decreases and some rules may become uninteresting. However while climbing up the hierarchy some new rules may become interesting.

This gives rise to *multilevel association rules* (Han et al., 1999), which capture linkages between items or attributes at different levels of abstraction, i.e. at different levels of concept hierarchy. For example, the rule $\{Brown\ Bread\} \rightarrow \{Coke\}$ captures linkages between items at different levels of concept hierarchy. Multilevel rules can be mined either using the same support thresholds or different thresholds at different levels.

Selecting an appropriate level of abstraction can have a significant impact on the usefulness of the knowledge generated. Mining at a very high level of abstraction is likely to generate over-generalized rules, which may not be interesting, while mining at too low an abstraction level may lead to generation of highly specific rules.

Figure 4. Concept hierarchy for food

3. **Multidimensional Association Rules:** Association rules essentially expose intra-record linkages. If links exist between different values of the same attribute (dimension), the association is called single-dimensional association rule, while if linkages span multiple dimensions, the associations are called multi-dimensional association rules (Kamber et al., 1997). For example the following single dimensional rule contains conjuncts in both antecedent and consequent from a single attribute 'buys'.

$Buys(X, "milk") \text{ and } Buys(X, "butter") \rightarrow Buys(X, "bread")$

Multidimensional associations contain two or more predicates, for example

$Age(X, "19-25") \text{ and } Occupation(X, "student") \rightarrow Buys(X, "coke")$

4. **Association Rules in Streaming Data:** The aforementioned types of rules pertain to static data repositories. Mining rules from data streams, however, is far more complex (Hidber, 1999). The field is relatively recent and poses additional challenges such as one-look characteristics of

data, limited main memory, continual updating of data and online processing so as to be able to make decisions on the fly (Cheng et al. 2007).

5. **Association Rule Mining with Multiple Minimum Supports:** In large departmental stores where the number of items is very large, using single support threshold sometimes does not yield interesting rules. Since buying trends for different items often vary vastly, the use of different support thresholds for different items is recommended (Liu et al., 1999).
6. **Negative Association Rules:** Typical association rules discover correlations between items that are bought during the transactions and are called positive association rules. Negative association rules discover implications in all the items, irrespective of whether they were bought or not. Negative association rules are useful in market-basket analysis to identify products that conflict with each other or complement each other. The importance of negative association rules was highlighted in (Brin et al., 1997; Wu et al. 2004).

FUTURE TRENDS

Though association analysis will continue to impact various scientific and business spheres through health-care databases, financial databases, spatial databases, multimedia databases and time series databases etc., we investigate the role of association rule mining in some promising applications.

Business Intelligence (BI): BI converts raw data into personalized intelligence with the goal of increasing customer satisfaction, loyalty and product profitability. It integrates data from multiple sources across company, analyzes it and acts promptly on the results leading to competitive advantage and timely deployment of solutions.

Association analysis is one of the core tools that support BI. In the retail sector association analysis provides basis for point-of-sale data analysis, market basket analysis, resources and space management optimization. In the banking realm, BI exploits the study of associations to perform credit risk analysis, fraud detection, and customer retention. The credit companies benefit by fraud detection, monitoring buying patterns, scoring customer reliability and analyzing cross-sell.

Stream data mining: In contrast to the data in traditional static databases, a data stream is an ordered sequence of items that is continuous, unbounded, usually comes with high speed and has a data distribution that changes with time. As the number of applications on mining data streams grows rapidly, there is an increasing need to perform association rule mining on stream data.

Association rules are employed in the estimation of missing data in streams of data generated by sensors and frequency estimation of internet packet streams. Association rule mining is also useful for monitoring manufacturing flows to predict failure or generate reports based on web log streams.

Bioinformatics: Associations are employed in bioinformatics databases for identification of co-occurring gene sequences. They are also used to detect gene mutations. A gene is a segment of a DNA molecule that contains all the information required for the synthesis of a product. Any change in the DNA sequence of a gene (For example: Insertion, Deletion, Insertion/Deletion, Complex and Multiple Substitution) is termed gene mutation. The discovery of interesting association relationships among huge amount of gene mutations is

important because it can help in determining the cause of mutation in tumours and diseases.

CONCLUSION

Association rule mining is an important data mining technique that was introduced to describe the intra record links in transactional databases. However, both academia and industry have seen the technology spell profitability and success due to its simplicity, ease of understanding and wide applicability. More than a decade later, the technology still promises to be the driving force for some new, challenging applications. No doubt that association rule mining has been regarded as one of the most significant contribution from the database community in KDD.

In this article, we introduced the notion of association rules, their applications and presented the mathematical formulation for the same. We also presented the major milestones in the development history of association rules. The general mining strategy, the related problems such as vastness of search space and the interestingness measures were also discussed. Finally, different types of association rules were described.

KEY TERMS

Association Rule: An implication of the form $X \rightarrow Y$, in a transactional data base with parameters support (s) and confidence (c). X and Y are set of items, s is the fraction of transactions containing $X \cup Y$ and c% of transactions containing X also contain Y.

Classification: Data mining technique that constructs a model (*classifier*) from historical data (training data) and uses it to predict the category of unseen tuples.

Clustering: Data mining technique to partition data objects into a set of groups such that the intra group similarity is maximized and inter group similarity is minimized.

Data Mining: Extraction of interesting, non-trivial, implicit, previously unknown and potentially useful information or patterns from data in large databases.

Data Stream: A continuous flow of data from a data source, e.g., a sensor, stock ticker, monitoring device, etc. A data stream is characterized by its unbounded size.

Descriptive Mining Technique: Data mining technique that induces a model describing the characteristics of data. These techniques are usually unsupervised and totally data driven.

Predictive Mining Technique: Data mining technique that induces a model from historical data in supervised manner, and uses the model to predict some characteristic of new data.

Automated Cryptanalysis

INTRODUCTION

Classical ciphers are used to encrypt plaintext messages written in a natural language in such a way that they are readable for sender or intended recipient only. Many classical ciphers can be broken by brute-force search through the key-space. One of the pertinent problems arising in automated cryptanalysis is the plaintext recognition. A computer should be able to decide which of many possible decrypts are meaningful. This can be accomplished by means of a text scoring function, based, e.g. on n -grams or other text statistics. A scoring function can also be used in conjunction with AI methods to speedup cryptanalysis.

BACKGROUND

Language recognition is a field of artificial intelligence studying how to employ computers to recognize language of a text. This is a simple task when we have enough amount of text with accents since they characterize used language with very high accuracy. Nowadays there are plenty of toolkits which automatically check/correct often both spelling and grammatical mistakes and errors. In connection with this we recall also the NIST Language Recognition Evaluation (LRE-05, LRE-07) as a part of an ongoing series of evaluations of language recognition technology. McMahon & Smith (1998) present an overview of natural language processing techniques based on statistical models.

We recall some basic notions from cryptography (see the article automated cryptanalysis of classical ciphers for more details). There is a reversible encryption rule (algorithm) how to transform plaintext to the ciphertext, and vice-versa. These algorithms depend on a secret parameter K called the key. The set of possible keys \mathcal{K} is called the key-space. Input and output of these algo-

rithms is a string of letters from plaintext, or ciphertext alphabet respectively. Both, sender as well as receiver, uses the same secret key, and the same encryption and decryption algorithms.

Cryptanalysis is a process of key recovery, or plaintext recovery without the knowledge of the key. In both cases we need a plaintext recognition subroutine which evaluates (with some probability) every candidate substring, whether it is a valid plaintext or not. Such automated text recognition requires an adequate model of a used language.

PLAINTEXT RECOGNITION FOR AUTOMATED CRYPTANALYSIS

In the process of automated cryptanalysis we decrypt the ciphertext with many possible keys to obtain candidate plaintexts. Most of the candidates are incorrect, having no meaning in a natural language. On the other hand, even the correct plaintext can be hard to recognize and with the wrong recognition routine can be missed altogether.

The basic type of algorithm suitable for automated cryptanalysis is a brute force attack. This attack is only feasible when key-space is searchable on computational resources available to an attacker. The average time needed to verify a candidate strongly influences the size of searchable key-space. Thus, the plaintext recognition is the most critical part of the algorithm from the performance point of view. On the other hand, only the most complex algorithms achieve really high accuracy of the plaintext recognition. Thus the complexity and accuracy of plaintext recognition algorithms must be carefully balanced.

A generic brute force algorithm with plaintext recognition can be described by the pseudo-code in Exhibit A.

Exhibit A.

| | |
|----------------|---|
| INPUT: | ciphertext string $Y = y_0 y_1 y_2 \dots y_n$ |
| OUTPUT: | ordered sequence S of possible plaintexts with their scores |

1. Let $S = \{ \}$
2. For each key $K \in \mathcal{K}$ do
 - 2.1. Let $X = d_K(Y)$ be a candidate plaintext.
 - 2.2. Compute **negative test predicate** $filter(X)$. If predicate is **true**, continue with step 2.
 - 2.3. Compute **fast scoring function** $fastScore(X)$. If $fastScore(X) < LIMIT$, continue with step 2.
 - 2.4. Compute **precise scoring function** $score(X)$. If $score(X) < LIMIT$, continue with step 2.
 - 2.5. Let $S = S \cup \{ \langle score(X), X \rangle \}$
3. Sort S by key $score(X)$ descending.
4. Return S .

Table 1. Performance of the three-layer decryption of a table-transposition cipher using a brute-force search. First filter was negative predicate-based, removing all decrypts with first 4 letters not forming a valid n -gram (about 90 % of texts were removed). Score was then computed as the count of valid tetragrams in the whole text. If this count was lower then given threshold (12), then the text was removed in the score-based filter. Finally, remaining texts were scored using the dictionary words.

| Key-space Size | Negative filter | Score-based filter | Remaining texts | Total time [s] |
|----------------|-----------------|--------------------|-----------------|----------------|
| 9! | 89.11% | 10.82% | 254 | 1.2 |
| 10! | 89.15% | 10.78% | 2903 | 5.8 |
| 11! | 88.08% | 8.92% | 239501 | 341 |
| 12! | 90.10% | 9.85% | 1193512 | 746 |

Algorithm integrates the three layers of plaintext recognition, namely *negative test predicate*, *fast scoring function* and *precise scoring function*, as a three-layer filter. The final scoring function is also used to sort the outputs. First filter should be very fast, with very low error probability. Fast score should be easy to compute, but it is not required to precisely identify the correct plaintext. Correct plaintext recognition is the role of precise scoring function. In the algorithm, the best score is the highest one. If the score is computed in the opposite meaning, the algorithm must be rewritten accordingly.

In some cases, we can integrate a fast scoring function within the negative test or with the precise scoring, leading to two-layer filters, as in (Zajac, 2006a). It is also possible to use even more steps of predicate-based and score-based filtering, respectively. However, experiments show that the proposed architecture of

three-layers is the most flexible, and more layers can even lead to performance decrease. Experimental results are shown in Table 1.

Negative Filtering

The goal of the *negative test predicate* is to identify candidate texts that are NOT plaintext (with very high probability, ideally with certainty). People can clearly recognize the wrong text just by looking at it. It is in the area of artificial intelligence to implement this ability in computers. However, most nowadays AI methods (e.g. neural networks) seem to be too slow, to be applicable in this stage of a brute-force algorithm, as every text must be evaluated with this predicate.

Most of the methods for fast negative text filtering are based on prohibited n -grams. As an n -gram

we would only consider a sequence of n consecutive letters. If the alphabet size is N , then it is possible to create N^n possible n -grams. For higher n , only a small fraction of them can appear in valid text in a given language (Zajac, 2006b). By using a lexical tree or lookup table, it is easy (and fast) to verify, whether a given n -gram is valid or not. Thus a natural test is to check every n -gram in the text, whether it is valid or not. There are two basic problems arising with this approach – the real plaintext can contain (intentionally) misspelled, uncommon or foreign words, and thus our n -gram database can be incomplete. We can limit our test to some specific patterns, e.g. too long run of consecutive vowels/consonants. These patterns can be checked in time dependent on the plaintext candidate length. A filter can also be based on checking only a few n -grams on a fixed or random position in the text, e.g. the first four letters.

The rule for rejecting texts should be based on the exact type of the cipher we are trying to decipher. For example, if the first four letters of the decrypted plaintext does not depend on some part of the key, the filter based only on their validity would not be effective. An interesting question is, whether it is possible to create a system which can effectively learn its filter rules from existing decrypted texts, even in the process of decryption.

Scoring Functions

With the negative filter step we can eliminate around 90% of candidate texts or more. The number of texts to be verified is still very huge, and thus we need to apply more precise methods of plaintext recognition. We use a scoring function that assigns a quantity – score – to every text that has survived elimination in previous steps. Here the higher score means higher likeness that a given text is a valid plaintext. For each scoring function we can assign a threshold, and it should be very improbable that a valid plaintext have score under this threshold. Actual threshold value can either be found experimentally (by evaluating large number of real texts), or can be based on a statistical analysis. Speed of the scoring function can be determined by using classical algorithm complexity estimates. Precision of the scoring can be defined by means of separation of valid and invalid plaintexts, respectively. There is a trade-off involved in scoring, as faster scoring functions are less precise and vice-versa. Thus we apply

two scoring functions: one that is fast but less precise, with lower threshold value, and one that is very precise, but harder to compute.

An example of scoring function distributions can be found in Figures 1 and 2. Scoring function in Figure 1 is much more precise than in Figure 2, but computational time required for evaluation is doubled. Moreover, scoring function in Figure 1 was created from a reduced dictionary fitted to a given ciphertext. Evaluation based on a complete dictionary is slower, more difficult to implement, and can even be less precise.

Scoring functions can be based on dictionary words, n -grams statistics, or other specific statistics. It is difficult to provide a one-fits-all scoring function, as decryption process for different cipher types has impact on actual scoring function results. E.g. when trying to decrypt a transposition cipher, we already know which letters appear with which frequency, and thus letter frequency based statistics do not play any role in scoring. On the other hand they are quite significant for substitution ciphers. Most common universal scoring functions are (see also Ganesan & Sherman, 1993):

1. **Number of dictionary words in the text / fraction of meaningful text**

Scoring based on dictionary words is very precise, if we have a large enough dictionary. Even if not every word in the hidden message is in our dictionary, it is very improbable that some incorrect decryption contains some larger fraction of a text composed of dictionary words. Removing short words from dictionary can increase the precision. Another possibility is to use weights based on word length as in (Russell, Clark & Stepney, 2003). Dictionary words can be found using lexical trees. In some languages, we should use dictionary of word stems, instead of the whole words. Speed of evaluation depends on the length of the text and the average length of words in dictionary, respectively.

2. **Rank distance of n -grams**

Rank of the n -gram is its position depending on order based n -gram frequencies (merged for all n up to given bound dependent on language). This method is used (Cavnar & Trenkle, 1994) in fast automated language recognition: compute ranks of n -grams of given text and compare it with ranks of significant n -grams obtained from large corpus of different languages. Correct language should

Figure 1. Distribution of score among $9!$ possible decrypts (table transposition cipher with key given by a permutation of 9 columns), ciphertext size is 90 characters. Score was computed as a weighted sum of lengths of (reduced) dictionary words found in the text. Single highest score belongs to the correct plaintext.

have the smallest distance. Even if this method can be adapted for plaintext recognition, e.g. by creating “random” corpus, or encrypted corpus, it does not seem practical.

3. Frequency distance of n -gram statistics

Score of the text can be estimated from the difference of measured frequency of n -grams and estimated frequencies from large corpus (Clark, 1998; Spillman, Janssen, Nelson & Kepner, 1993). We suppose that correct plaintext would have the smallest distance from corpus statistics. However due to statistical properties of the text, this is not always true for short or specific texts. Thus the precision of this scoring function is higher for longer texts. Speed of the evaluation depends on the text size and size of n .

4. Scoring tables for n -grams

If we consider the statistics of all n -grams, we will see that most n -grams contribute a very small value to the final score. We can consider contribution of only the most common n -grams. For a given language (and a given ciphertext) we can prepare a table of n -gram scores with fixed number of entries. Score is evaluated as the sum of scores assigned to n -grams in a given candidate text (Clark & Dawson, 1998). We can assign both positive scores for common valid n -grams, and negative scores for common invalid/supposedly rare n -grams. However, precision of this method

is very low especially for transposition ciphers. In our experiments the scores have normal distribution, and usually the correct plaintext does not have highest possible values. On the other hand, this scoring function is easy to evaluate, and can be customized for a given ciphertext. Thus it can be used as a fast scoring function $fastScore(X)$.

5. Index of coincidence (and other similar statistics)

Index of coincidence (Friedman 1920), denoted by I_C , is a suitable and fast statistics applicable for ciphers that modify the letter frequency. The notion comes from probability of the same letter occurring in two different texts at the same position. Encrypted texts are considered random, and have (normalized) index of coincidence near to the 1.0. On the other hand, a plaintext has much higher I_C near the value expected for a given language and alphabet. For English language the expected value is 1.73. As with all statistics based on scoring function, its precision is influenced by the length of the text. Index of coincidence is most suitable for polyalphabetic ciphers, where encryption depends on the position of the letter in the text (e.g. Vigenère cipher). It can be adapted to other cipher types (Bagnall, McKeown & Rayward-Smith, 1997), e.g. for transposition ciphers when considering that alphabet is created by all possible n -grams with some $n > 1$.

Figure 2. Distribution of score among 9! possible decrypts (table transposition cipher with key given by a permutation of 9 columns), ciphertext size is 90 characters. Score is the count of digrams with frequency higher than 1% (in Slovak language) in a given text. The correct plaintext has scored 73.

FUTURE TRENDS

Language processing and recognition have applications in various areas outside cryptanalysis (OCR, automatic translation...). Some cryptanalytic techniques can be generalized for these fields. E.g. some letters or groups of letters are often replaced by another in scanned documents. Thus correcting these documents is similar to cryptanalysis of randomized substitution ciphers. With Artificial Intelligence research new insights can be gained into a structure of natural language that can help further in cryptanalysis. Cryptanalysis is also strongly related to automatic translation efforts.

Some open problems that need to be addressed by language recognition suitable for cryptanalysis of classical ciphers are the following:

- How the text recognition should be integrated with decryption process to give feedback, e.g. on partially decrypted words, to estimate a new key, etc. This is especially true, if we use more advanced search heuristic than brute-force search through the key-space. This can also be viewed as a generalization of results of Peleg & Rosenfeld (1979).
- How the syntax and semantics of the language can help in text recognition and key search, respectively.

- How various encodings and writing systems influence cryptanalysis. Specific issues arise when dealing with different writing systems (Atkinson 1985; August 1989 and 1990).
- How to correctly recognize text with intentional misspellings and special code words.

Another set of problems arises when different natural languages are used, like the language recognition, specific alphabets, impact of diacritical marks, etc. Our research shows that the language of the message encrypted by substitution cipher can be recognized even without decryption (Zajac, 2006b). It is even possible to use dictionary of a different (although similar) language in decryption process. It is an interesting research question whether it is possible to create completely general language recognition function (or restricted to some family of languages) usable for cryptanalysis.

Plaintext recognition in cryptanalysis can be also seen as a specific information retrieval problem (Manning, Raghavan & Schütze 2008). Multilanguage information retrieval is targeting similar problems to the problems presented above (see e.g. McNamee, 2006). The research in these areas can clearly influence each other in the future.

CONCLUSION

This article summarizes the usage and restrictions for language processing in the context of cryptanalysis of classical ciphers. Their application usually differs according to a character of the analyzed cipher systems, although we have presented some common techniques that can be easily adapted for a specific situation. Most cryptanalytic attacks require very fast language recognition, but on the other hand, great speed often causes inaccurate results, up to the point of unrecognizable decrypts. The role of the Artificial Intelligence research is to find faster and more precise language predicates and combine them to a useful plaintext recognition system.

KEY TERMS

Brute-Force Attack: Exhaustive cryptanalytic technique that searches the whole key-space to find the correct key.

Candidate Text: The text that was obtained by application of decryption algorithm on ciphertext using some key $k \in \mathcal{K}$. If k is the correct key (or the equivalent)

lent key to) K , then candidate text is a valid plaintext x , otherwise it is a text encrypted by concatenation of $d_k(e_k(x))$.

Ciphertext: The encrypted text, a string of letters from alphabet C of a given cryptosystem by a given key $K \in \mathcal{K}$.

Classical Cipher: A classical cipher system is a five-tuple $(\mathcal{P}, \mathcal{C}, \mathcal{K}, \mathcal{E}, \mathcal{D})$, where \mathcal{P} , \mathcal{C} , define plaintext and ciphertext alphabet, \mathcal{K} is the set of possible keys, and for each $K \in \mathcal{K}$ there exists an encryption algorithm $e_K \in \mathcal{E}$, and a corresponding decryption algorithm $d_K \in \mathcal{D}$ such that $d_K(e_K(x)) = x$ for every input $x \in \mathcal{P}$ and $K \in \mathcal{K}$.

Cryptanalysis: Is a process of trying to decrypt given ciphertext and/or find the key without, or with only partial knowledge of the key. It is also a research area studying techniques of cryptanalysis.

Key-Space: Set of all possible keys for a given ciphertext. Key-space can be limited to a subspace of the whole \mathcal{K} by some prior knowledge.

Plaintext: The unencrypted text, a string of letters from alphabet \mathcal{P} of a given cryptosystem.

Plaintexts Filter: An algorithm, or predicate, used to determine, which texts are not valid plaintexts. Ideal plaintexts filter never produces answer INVALID for a correct plaintext.

Scoring Function: Scoring function is used to evaluate fitness of a candidate text for a key $k \in \mathcal{K}$. Ideal scoring function has global extreme in the correct plaintext, i.e. when $k = K$.

Automated Cryptanalysis of Classical Ciphers

Otokar Grošek

Slovak University of Technology, Slovakia

Pavol Zajac

Slovak University of Technology, Slovakia

INTRODUCTION

Classical ciphers are used to encrypt plaintext messages written in a natural language in such a way that they are readable for sender or intended recipient only. Many classical ciphers can be broken by brute-force search through the key-space. Methods of artificial intelligence, such as optimization heuristics, can be used to narrow the search space, to speed-up text processing and text recognition in the cryptanalytic process. Here we present a broad overview of different AI techniques usable in cryptanalysis of classical ciphers. Specific methods to effectively recognize the correctly decrypted text among many possible decrypts are discussed in the next part Automated cryptanalysis – Language processing.

BACKGROUND

Cryptanalysis can be seen as an effort to translate a ciphertext (an encrypted text) to a human language. Cryptanalysis can thus be related to the computational linguistics. This area originated with efforts in the United States in the 1950s to have computers automatically translate texts from foreign languages into English, particularly Russian scientific journals. Nowadays it is a field of study devoted to developing algorithms and software for intelligently processing language data. Systematic (public) efforts to automate cryptanalysis using computers can be traced to first papers written in late '70s (see e.g. Schatz, 1977). However, the research area has still many open problems, closely connected to an area of Artificial Intelligence. It can be concluded from the current state-of-the-art, that although computers are very useful in many cryptanalytic tasks, a human intelligence is still essential in complete cryptanalysis.

For convenience of a reader we recall some basic notions from cryptography. Very thorough survey of classical ciphers is written by Kahn (1974). A message to be encrypted (plaintext) is written in the lowercase alphabet $\mathcal{P} = \{a, b, c \dots x, y, z\}$. The encrypted message (ciphertext) is written in uppercase alphabet $\mathcal{C} = \{A, B, C \dots X, Y, Z\}$. Different alphabets are used in order to better distinguish plaintext and ciphertext, respectively. In fact these alphabets are the same.

There is a reversible encryption rule (algorithm) how to transform the plaintext to the ciphertext, and vice-versa. These algorithms depend on a secret parameter K called the key. The set of possible keys \mathcal{K} is called the key-space. Input and output of these algorithms is a string of letters from respective alphabets, \mathcal{P}^* and \mathcal{C}^* . Both, sender as well as receiver, uses the same secret key, and the same encryption and decryption algorithms.

There are three basic classical systems to encrypt a message, namely a substitution, a transposition, and a running key. In a substitution cipher a string of letters is replaced by another string of letters using prescribed substitution of single letters, e.g. left 'a' to 'A', replacing letter 'b' by letter 'N', letter 'c' by letter 'G', etc. A transposition cipher rearranges order of letters according to a secret key K . Unlike substitution ciphers the frequency of letters in the plaintext and ciphertext remains the same. This characteristic is used in recognizing that the text was encrypted by some transposition cipher. A typical running key cipher is to derive from a main key K the running key $K_0 K_1 K_2 \dots K_n$. If $\mathcal{P} = \mathcal{C} = \mathcal{K}$ is a group, then simply $y_i = e_K(x_i) = x_i + K_i$.

Thus it is convenient to define a ciphering algorithm for classical ciphers as follows:

Definition 1: A classical cipher system is a five-tuple $(\mathcal{P}, \mathcal{C}, \mathcal{K}, \mathcal{E}, \mathcal{D})$, where the following conditions are satisfied:

1. \mathcal{P} is a finite set of a plaintext alphabet, and \mathcal{P}^* the set of all finite strings of symbols from \mathcal{P} .
2. \mathcal{C} is a finite set of a ciphertext alphabet, and \mathcal{C}^* the set of all finite strings of symbols from \mathcal{C} .
3. \mathcal{K} is a finite set of possible keys.
4. For each $K \in \mathcal{K}$, there is an encryption algorithm $e_K \in \mathcal{E}$, and a corresponding decryption algorithm $d_K \in \mathcal{D}$ such that $d_K(e_K(x)) = x$ for every input $x \in \mathcal{P}$ and $K \in \mathcal{K}$.
5. The ciphering algorithm assigns to any finite string $x_0 x_1 x_2 \dots x_n$ from \mathcal{P}^* the resulting ciphertext string $y_0 y_1 y_2 \dots y_n$ from \mathcal{C}^* , where $y_i = e_K(x_i)$. The actual key may, or need not depend on the index i .

Another typical case for \mathcal{P} , and \mathcal{C} , are r -tuples of the Latin alphabet. For transposition ciphers, the key is periodically repeated for r -tuples. For substitution ciphers of r -tuples, the key is an r -tuple of keys. In the case of running keys, there is another key stream generator $g: \mathcal{K} \times \mathcal{P} \rightarrow \mathcal{K}$ which generates from the initial key K , and possibly from the plaintext $x_0 x_1 x_2 \dots x_{n-1}$ the actual key K_n .

For classical ciphers, there are two typical situations when we try to recover the plaintext:

1. Let the input to decryption algorithm $d_K \in \mathcal{D}$ with unknown key K be a ciphertext string $y_0 y_1 y_2 \dots y_n$ from \mathcal{C}^* , where $y_i = e_K(x_i)$. Our aim is to find the plaintext string $x_0 x_1 x_2 \dots x_n$ from \mathcal{P}^* . Thus in each execution an algorithm is searching through Key-space \mathcal{K} .
2. The decryption algorithm $d_K \in \mathcal{D}$ and key K are unknown. Our aim is to find for the ciphertext string $y_0 y_1 y_2 \dots y_n$ from \mathcal{C}^* , where $y_i = e_K(x_i)$, the plaintext string $x_0 x_1 x_2 \dots x_n$ from \mathcal{P}^* . This requires a different algorithm than the actual $d_K \in \mathcal{D}$, as well as some additional information. Usually there is available another ciphertext, say $z_0 z_1 z_2 \dots z_n$ from \mathcal{C}^* . Thus in each execution an algorithm is searching through possible substitutions which are suitable for both ciphertexts.

In both cases we need a plaintext recognition subroutine which evaluates a candidate substring of length v for a possible plaintext, say $c_t c_{t+1} c_{t+2} \dots c_{t+v} := x_t x_{t+1} x_{t+2} \dots x_{t+v}$. Such automated text recognition needs an adequate model of a used language.

AUTOMATED CRYPTANALYSIS

There are two straightforward methods for automated cryptanalysis. Unfortunately none of them is for longer strings applicable in practice. The first one is for transposition ciphers. When no other information about the cipher is known, we can use a general method, called anagramming, to decipher the message. In this method we are trying to assemble the meaningful string (anagram) from the ciphertext. This is accomplished by arranging the letters to words from the dictionary. When we find the meaningful word we process the rest of the message in the same way. When we are not able to create more meaningful words, we retrace our steps, and try other possible words until the whole meaningful anagram is found.

The second, and very similar, is for the substitution ciphers. Here we are trying to assemble the meaningful string (anagram) from the ciphertext by searching through all possible substitutions of letters to get words from dictionary of the used language. Although the size of the key-space is large, automated cryptanalysis uses many other methods based, e.g. on frequency distribution of letters. Automated cryptanalysis of simple substitution ciphers can decrypt most of the messages both with known word boundaries (Carroll & Martin, 1986), and without this information (Ramesh, Athithan & Thiruvengadam, 1993; Jakobsen, 1995). There are other classical ciphers, where transposition or substitution depends not only on the actual key, but also on a position within a block of letters of the string.

For effective automated cryptanalysis at least two layers of plaintext candidate processing, filtering and scoring, are required. Better results are achieved by additional filtering layers. This of course increases computational complexity. Below we give an overview of these filtering layers.

Automated Brute Force Attacks

The basic type of algorithm suitable for automated cryptanalysis is a brute force attack. As we have to search the whole key-space, this attack is only feasible when key-space is “not too large”. Exact quantification of the searchable key-space depends on computational resources available to an attacker, and the average time needed to verify a candidate for decrypted text. Thus, the plaintext recognition is the most critical part of the algorithm from the performance point of view.

On the other hand, only the most complex algorithms achieve really high accuracy of plaintext recognition. Thus the careful balance of the complexity of plaintext recognition algorithms and its accuracy is required. It is unlikely that automated cryptanalysis produces only one possible result, but it is possible to limit the set of possible decrypts to a manageable size. Reported results should be sorted according to their probability of being the true plaintext.

A generic brute force algorithm with plaintext recognition can be described by the pseudo-code in Exhibit A.

We have identified three layers of plaintext recognition, namely *negative test predicate*, *fast scoring function* and *precise scoring function*. All three functions are used as a three-layer filter, and final scoring function is also used to sort the outputs. First filter should be very fast, and should have very low error probability. Fast score should be easy to compute, but it is not required to precisely identify the correct plaintext. Correct plaintext recognition is the role of precise scoring function. In the algorithm, the best score is the highest one. If the score is computed in the opposite meaning, the algorithm must be rewritten accordingly.

In some cases, we can integrate a fast scoring function within negative test or with the precise scoring, leading to two-layer filters, as in (Zajac, 2006a). It is also possible to use even more steps of predicate-based and score-based filtering, respectively. However, experiments show that the proposed architecture of three-layers is the most flexible, and more layers can even lead to performance decrease. Scoring and fil-

tering is described in-depth in the article Automated cryptanalysis – Language processing.

Applications of Artificial Intelligence Methods

Artificial Intelligence (AI) methods can be used in four main areas of the automated cryptanalysis:

1. *Plaintext recognition*: The goal of the AI is to supply negative predicates that filter out wrong decrypts, and scoring functions that assess the text's likeness to natural language.
2. *Key-search heuristics*: The goal of the AI is to provide heuristics to speed-up the decryption process either by constraining the key-space, or by guiding the selection of next keys to be tried in the decryption. This area is most often researched, as it can provide clear experimental results, and meaningful evaluation.
3. *Plaintext estimation*: The goal of the AI is to estimate the meaning of the plaintext from the partial decryption, or to estimate some parts of the plaintext based on external data (e.g. a sender of a ciphertext, historical and geographic context, specific grammatical rules etc.) Estimated parts of the plaintext can then lead to much easier complete decryption. This area of research is mainly unexplored, and plaintext estimation is done by the cryptanalyst.
4. *Automatic security evaluation*: The goal of the cryptanalysis is not only to break ciphers and to

learn secrets, but it is also used when creating new ciphers to evaluate their security. Although most classical ciphers are already “outdated”, their cryptanalysis is still important, e.g. in teaching the modern computer security principles. When teaching classical ciphers, it is useful to have an AI tool (e.g. an expert system), that can automate the evaluation of cipher security (at least under some weaker assumptions). Although much work is done in automatic evaluation of modern security protocols, we are unaware of some tools to evaluate “classical” cipher designs.

Area that is best researched is the area of *Key-search heuristics*. It immediately follows from the fact that brute force search through the whole key-space can be considered as a very crude method of decryption. Most classical ciphers were not designed with careful consideration of the text statistics. We can assign score for each key in the key-space that is correlated with the probability that text decrypted by given key is the plaintext. The score, when considered over the key-space, certainly have some local maxima, which can lead either immediately to a meaningful plaintext, or a text from which plaintext is easily guessed. Thus it can be useful to consider various relaxation techniques to search through the key-space with the goal of maximizing scoring function. One of the earliest demonstrations of relaxation techniques for breaking substitution ciphers are presented by Peleg & Rosenfeld (1979) and Hunter & McKenzie (1983). Successful attacks applicable for many classical ciphers can be implemented using basic hill climbing, through tabu search, simulated annealing and applications of genetic/evolution algorithms (Clark & Dawson, 1998). Genetic algorithms have achieved many successes in breaking classical ciphers as demonstrated by Mathews (1993), or Clark (1994), and can even break a rotor machine (Bagnall, McKeown & Rayward-Smith, 1997). Russell, Clark & Stepney (1998) present anagramming attack using a solver based on an ant colony optimisation algorithm.

These types of attack try to converge to the correct key by small changes of the actual key. Success rate of the attacks is usually measured by the fraction of the reconstructed key and/or text. Relaxation methods can find with a high probability the keys, or the plaintext approximations, even if it is not feasible to search the whole key-space. The success mainly depends on the ciphertext size, since the scoring is usually statistics-

based. One of the unexplored challenges is to consider application of multiple relaxation techniques. First heuristic can be used to shrink the key-space, and then either the brute-force search or another heuristic is used with more precision to finish the decryption.

FUTURE TRENDS

The results obtained strongly depend on the size of the ciphertext, and decryptions are usually only partial. Techniques of the automated cryptanalysis also need to be fitted to a given problem. E.g. attacks on substitution ciphers can use individual letter statistics, but for attacks intended for transposition ciphers these statistics are invariant and make no sense in using. Automated cryptanalysis is usually studied only in context of these two main types of ciphers, but there is a broad area of unexplored problems concerning different classical cipher types, such as running key type ciphers. Specific uses of AI techniques can fail for some cryptosystems as pointed by Wagner, S., Affenzeller, M. & Schragl, D. (2004). Cryptanalysis also depends on the language (Zajac, 2006b), although there are some notable exceptions when considering similar languages.

As the computational power increases, even just recently used ciphers, like Data Encryption Standard (DES), are becoming subject of automated cryptanalysis (e.g. Nalini & Raghavendra Rao, 2007). Beside application of heuristics to cryptanalysis, a lot of further research is required in areas of plaintext estimation and automatic security evaluation. An expert system that would cover these areas and connect them with AI for plaintext recognition and search heuristics can be a strong tool to teach computer security or to help forensic analysis or historical studies involving encrypted materials.

CONCLUSION

This article is concerned with an automated cryptanalysis of classical ciphers, where classical ciphers are considered as a cipher from before WW2, or pencil-and-paper ciphers. Optimization heuristics are quite successful in attacks targeted to these ciphers, but they usually cannot be made fully-automatic. Their application usually differs according to a character of the analysed cipher systems. An important research

direction is extending the techniques from classical cryptanalysis to automated decryption of modern digital cryptosystems. Another important problem is to create set of fully-automatic cryptanalytic tools or a complete expert system that can be adapted to various types of ciphers and languages.

KEY TERMS

Brute-Force Attack: Exhaustive cryptanalytic technique that searches the whole key-space to find the correct key.

Ciphertext: The encrypted text, a string of letters from alphabet C of a given cryptosystem by a given key $K \in \mathcal{K}$.

Classical Cipher: A classical cipher system is a five-tuple $(\mathcal{P}, \mathcal{C}, \mathcal{K}, \mathcal{E}, \mathcal{D})$, where \mathcal{P}, \mathcal{C} , define plaintext and ciphertext alphabet, \mathcal{K} is the set of possible keys, and for each $K \in \mathcal{K}$ there exists an encryption algorithm $e_K \in \mathcal{E}$, and a corresponding decryption algorithm $d_K \in \mathcal{D}$ such that $d_K(e_K(x)) = x$ for every input $x \in \mathcal{P}$ and $K \in \mathcal{K}$.

Cryptanalysis: Is a process of trying to decrypt given ciphertext and/or find the key without, or with only partial knowledge of the key. It is also a research area studying techniques of cryptanalysis.

Key-Space: Set of all possible keys for a given ciphertext. Key-space can be limited to a subspace of the whole \mathcal{K} by some prior knowledge.

Plaintext: The unencrypted text, a string of letters from alphabet \mathcal{P} of a given cryptosystem.

Relaxation Attack: Cryptanalytic technique that searches the key-space by incremental updates of the candidate key(s). It usually applies the knowledge of previous trial decryption(s) to change some parts of the key.

Automatic Classification of Impact–Echo Spectra I

INTRODUCTION

We investigate the application of artificial neural networks (ANNs) to the classification of spectra from impact-echo signals. In this paper we provide analyses from simulated signals and the second part paper details results of lab experiments.

The data set for this research consists of sonic and ultrasonic impact-echo signal spectra obtained from 100 3D-finite element models. These spectra, along with a categorization of the materials among homogeneous and defective classes depending on the kind of material defects, were used to develop supervised neural network classifiers. Four levels of complexity were proposed for classification of materials as: material condition, kind of defect, defect orientation and defect dimension. Results from Multilayer Perceptron (MLP) and Radial Basis Function (RBF) neural networks with Linear Discriminant Analysis (LDA), and k-Nearest Neighbours (kNN) algorithms (Duda, Hart, & Stork, 2000), (Bishop C.M., 2004) are compared. Suitable results for LDA and RBF were obtained.

The impact-echo is a technique for non-destructive evaluation based on monitoring the surface motion resulting from a short-duration mechanical impact. It has been widely used in applications of concrete structures in civil engineering. Cross-sectional resonant modes in impact-echo signals have been analyzed in elements of different shapes, such as, circular and square beams, beams with empty ducts or cement fillings, etc. In addition, frequency analyses of the displacement of the fundamental frequency to lower values for detection of cracks have been studied (Sansalone & Street, 1997), (Carino, 2001).

The impact-echo wave propagation can be analyzed from transient and stationary behaviour. The excitation signal (the impact) produces a short transient stage where the first P (normal stress), S (shear stress) and

Rayleigh (superficial) waves arrive to the sensors; afterward the wave propagation phenomenon becomes stationary and a manifold of different mixtures of waves including various changes of S-wave to P-wave propagation mode and viceversa arrive to the sensors. Patterns of waveform displacements in this latter stage are known as the resonant modes of the material. The spectra of impact-echo signals provide of information for classification based on resonant modes the inspected materials. The classification tree approached in this paper has four levels from global to detailed classes with up to 12 classes in the lowest level. The levels are: (i) Material condition: homogeneous, one defect, multiple defects, (ii) Kind of defect: homogeneous, hole, crack, multiple defects, (iii) Defect orientation: homogeneous, hole in axis X or axis Y, crack in planes XY, ZY, or XZ, multiple defects, and (iv) Defect dimension: homogeneous, passing through and half passing through types of holes and cracks of level iii, multiple defects. Some examples of defective models are in Figure 1.

BACKGROUND

Neural networks applications in impact-echo testing include: detect flaws on concrete slabs, combining spectra of numerical simulations and real signals for network training (Pratt & Sansalone, 1992), identification of unilaterally working sublayer cracks using numerically generated waveforms as network inputs (Stavroulakis, 1999), classification of concrete slabs in solid and defective (containing void or delamination), use of training features extracted from many repetitions of impact-echo experiments on three specimens to be classified in three classes (Xiang & Tso, 2002), and to predict shallow crack depths in asphalt pavements using features from an extensive real signal

dataset (Mei, 2004). All these studies used multilayer perceptron neural network and monosensor impact-echo systems.

In a recent work, we classified impact-echo data by neural networks using temporal and frequency features extracted from the signals, finding that the better features were frequency features (Salazar, Uni6, Serrano, & Gosalbez, 2007). Thus the present work is focused in exploiting only spectra information of the impact-echo signals. These spectra contain a large amount of redundant information. We applied Principal Component Analysis (PCA) to spectra for compressing and removing noise. The proposed classification problem and the use of spectra PCA components as classification features are a new proposal in application of neural networks to impact-echo testing.

There is evidence that the first components of PCA retain essentially all of the useful information and this compression optimally removes noise and can be used to identify unusual spectra (Bailer-Jones, 1996), (Bailer-Jones, Irwin, & Hippel, 1998), (Xu et al., 2004). The principal components represent sources of variance in the data. The projection of the p^{th} spectrum onto the k^{th} principal component is known as the admixture coefficient $a_{k,p}$. The most significant principal components contain those features which are most strongly correlated in many of the spectra. It follows that noise (which is uncorrelated with any other features by definition) will be represented in the less significant components. Thus by retaining only the more significant components to represent the spectra we achieve a data compression that preferentially remove noise. The reduced reconstruction, \mathbf{y}_p of the p^{th} spectrum \mathbf{x}_p , is obtained by using only the first r principal components to reconstruct the spectrum, i.e.

$$\mathbf{y}_p = \bar{\mathbf{x}} + \sum_{k=1}^{k=r} a_{k,p} \mathbf{u}_k, \quad r < N, \quad (1)$$

where $\bar{\mathbf{x}}$ is the mean spectrum which is subtracted from the spectra before the eigenvectors are calculated, and \mathbf{u}_k is the k^{th} principal component. $\bar{\mathbf{x}}$ can be considered as the zeroth eigenvector, although the degree of variance it explains depends on the specific data set and may be much less than that explained by the first eigenvectors.

Let ε_p be the error incurred in using this reduced reconstruction. By definition $\mathbf{x}_p = \mathbf{y}_p + \varepsilon_p$, so

$$\varepsilon_p = \sum_{k=r+1}^{k=N} a_{k,p} \mathbf{u}_k. \quad (2)$$

RECOGNITION OF DEFECT PATTERNS IN IMPACT-ECHO SPECTRA -SIMULATIONS

Impact-Echo Signals

Simulated signals came from full transient dynamic analysis of 100 3D finite element models of simulated parallelepiped-shape material of 0.07x0.05x0.22m. (width, height and length) supported to one third and two thirds of the block length (direction z). Figure 1 shows different examples of the models of defective pieces. From the transient analysis the dynamic response of the material structure (time-varying displacements in the structure) under the action of a transient load is estimated. The transient load, i.e. the hammer impact, was simulated by applying a force-time history of a half sine wave with a period of 64 μ s as a uniform pressure load on two elements at the centre of the model front face. The elastic material constants for the simulated material were: density 2700 kg/m³, elasticity modulus 69500 Mpa. and Poisson's ratio 0.22.

Elements having dimensions of about 0.01 m. were used in the models. These elements can accurately capture the frequency response up to 40 kHz. Surface displacement waveforms were taken from the simulation results at 7 nodes in different locations on the material surface, see Figure 1a. Signals consisted of 5000 samples recorded at a sampling frequency of 100 kHz. To make possible to compare simulations with experiments, the second derivative of the displacement was calculated to work with accelerations, since the sensors available for experiments were mono-axial accelerometers. These accelerations were measured in the normal direction to the plane of the material surface accordingly to the configuration of the sensors in Figure 1a.

Feature Extraction and Selection

We investigate if the changes in the spectra, particularly in the zones of the fundamental frequencies, are related

Figure 1. Finite element models with different defects and 7-sensor configuration

1a. Half-passing through crack oriented in plane YZ 1b. passing through hole oriented in axis Y

with the shape, orientation and dimension of the defects. The information of the spectra for each channel consists of $n/2$ values as half of the number of points used to calculate the Fast Fourier Transform (FFT). Due to the 7-channel impact-echo system setup applied, the number of data available for each impact-echo test was $7 \cdot n/2$, e.g. for a FFT calculated with 256 points, 896 values would be available as entries for classifiers. This high number of entries could be unsuitable for the training stage of neural networks. Considering impact-echo signal spectra redundancy, PCA was applied in two steps. At first step, PCA was applied to the spectra of each channel as a feature extraction method. At second step, PCA was applied to the component set (spectra compressed) obtained in the first step for all the channels and records as dimensionality reduction and feature selection method. Thus, a compressed and representative pattern of the spectra for the multichannel impact-echo inspection was obtained.

The size of the FFT employed was 1024 points since using less points the resolution was not good enough for classifications. Once the spectra were estimated for all the models they were grouped and normalized by maximum per channel. There were considered three options to establish the number of components at the first PCA step: select a number of components that explain a minimum of the variance in the data, or a number of components such the variance increment is minimum, or a fixed number of components. The

first two options could estimate a variable number of components per channel, and they could select more components for the channels with 'worst' signals, i.e. signals with low signal to noise relation (SNR), due to problems in measuring (e.g. bad contact in the interface sensor and material). Thus we select a fixed number of components=20 per channel, that explained more than 95% of the data variance for each of the channels, so the total number of components was $7 \cdot 20 = 140$ for one model.

The initial entries for the classification stage were then 140 features (spectra components) for the 100 simulation models. For simulations 20 replicates for each model were added that corresponded to the repetitions performed in the experiments. The replicates were generated using random Gaussian noise with 0.1-standard deviation of the original signals; then total of records for simulations was 2000 with 140 spectra components.

PCA was applied again to reduce the dimensionality of the classification space and to select the best spectra features for classification. After some preliminary tests, 50 was set as a number of components for classification. Using this number of components, the explained variance was 98%. With the 50 sorted components obtained, an iterative process of classification varying the number of components was applied using LDA and kNN as classifiers. The curve described by the set of classification error and number of components (5,10,15,...,50)

values has an inflection point where the information provided for the components perform the best classification. Following this feature selection process, a reduced set of features ('better' spectra components) was obtained. Those features were used as entries for ANNs, improving the performance of the classification, instead of using all the spectra components. The number of selected components for ANN classification varied from 20 to 30, depending on classification level (material condition, kind of defect, defect orientation, defect dimension).

The classification proceeded applying the Leave-One-Out method, avoiding records of replicas or repetitions of a test piece were in the training stage of that piece, so generalization of pattern learning was forced. Thus some of the records used in training and test corresponded to models or specimens with the same kind of defect but located in different positions, and the rest of records corresponded to others kind of defective pieces. Results presented in next sections are referring to mean error in testing stage.

Simulation Results

Figure 2a shows the results of classification by kNN and LDA with linear, Mahalanobis, and quadratic distances for simulations at level 4 of the classification tree. The best percentage of classification success (75.9) is obtained by LDA-quadratic and LDA-Mahalanobis with 25 components. Those components were selected and used as inputs for the input layer of the networks. One hidden layer was used (different number of neurons were tried to obtain the best configuration of the neuron number at this layer), and the number of neurons at the output layer was set as the number of classes, depending on the classification level. A validation stage and resilient propagation training method were used in classifications with MLP. The spread parameter was tuned for RBF, Figure 2b shows how the spread affects the classification results in the "defect dimension level", and in this case the minimum error (0.31) is for spread value 1.6.

Summarised general results by different classification methods for simulations are showed in Table 1. The best classification performance is obtained by LDA with quadratic distance, but results of RBF are fairly comparable. Due to classes are not equally-probable at each level, general results are weighted by class probability, see Figure 3. Homogeneous class was

completely distinguishable and multiple-defects class was the worst classified at every classification levels. The percentage of success could be very much higher by increasing classification success for multiple-defect class. This fact was caused because the multiple-defects models consisted in models with various cracks, and it yield confusion between the crack and multiple-defect classes. The percentage of success decreases for more complex classifications, with RBF lowest performance of 69% for 12 classes.

FUTURE TRENDS

The proposed methodology was tested with particular kind of material and defects and configuration of multichannel testing. It could be tested using models and specimens of different materials, sizes, sensor configurations, and signal processing parameters.

There exist several techniques and algorithms of classification that can be explored for the proposed problem. Recently a model of independent component analysis (ICA) was proposed for impact-echo (Salazar, Vergara, Igual, Gosalbez, & Miralles, 2004), and new classifiers based on mixtures of ICAs have been proposed (Salazar, Vergara, Igual, & Gosalbez, 2005), (Salazar, Vergara, Igual, & Serrano, 2007), that include issues as semisupervision in training stage. The use of prior knowledge in the training stage is critical in order to obtain suitable models for different kind of classifications. Those kind of techniques could give more understating on how labelled and labelled data change model learned by the classifier. In addition more research is needed on the shape of the classification space (impact-echo signal spectra), outlier probability, and decision region of the classes for the proposed problem.

CONCLUSION

We demonstrate the feasibility of using neural networks to extract patterns of different kinds of defects from impact-echo signal spectra in simulations. The methodology used was very restricted because there was only one piece for a defect in certain localization in the bulk and it was not in the training stage, so classifier had to assign the right class with the patterns of pieces of the same class in other localizations. Results could

KEY TERMS

Artificial Neural Network (ANN): A mathematical model inspired in biological neural networks. The units are called neurons connected in various input, hidden and output layers. For a specific stimulus (numerical data at the input layer) some neurons are activated following an activation function and producing numerical output. Thus ANN is trained, storing the learned model in weight matrices of the neurons. This kind of processing has demonstrated to be suitable to find nonlinear relationships in data, being more flexible in some applications than models extracted by linear decomposition techniques.

Finite Element Method (FEM): It is a numerical analysis technique to obtain solutions to the differential equations that describe, or approximately describe a wide variety of problems. The underlying premise of FEM states that a complicated domain can be sub-divided into a series of smaller regions (the finite elements) in which the differential equations are approximately

solved. By assembling the set of equations for each region, the behavior over the entire problem domain is determined.

Impact-Echo Testing: A non-destructive evaluation procedure based on monitoring the surface motion resulting from a short-duration mechanical impact. From analyses of the vibrations measured by sensors, a diagnosis of the material condition can be obtained.

Non-Destructive Evaluation (NDE): NDE, ND Testing or ND Inspection techniques are used in quality control of materials. Those techniques do not destroy the test object and extract information on the internal structure of the object. To detect different defects such as cracking and corrosion, there are different methods of testing available, such as X-ray (where cracks show up on the film), ultrasound (where cracks show up as an echo blip on the screen) and impact-echo (cracks are detected by changes in the resonance modes of the object).

Pattern Recognition: An important area of research concerned to discover or identify automatically figures, characters, shapes, forms, and patterns without active human participation in the decision process. It is also

related with classify data in categories. Classification consists in learning a model for separating the data categories, that kind of *machine learning* can be approached using statistical (parametric or no-parametric models) or heuristic techniques. If some prior information is given in learning process, it is called supervised or semi-supervised, else it is called unsupervised.

Principal Component Analysis (PCA): A method for achieving a dimensionality reduction. It represents a set of N -dimensional data by means of their projections onto a set of r optimally defined axes (principal components). As these axes form an orthogonal set, PCA yields a data linear transformation. Principal components represent sources of variance in the data. Thus the most significant principal components show those data features which vary the most.

Signal Spectra: Set of frequency components decomposed from an original signal in time domain. There exist several techniques to map a function in time domain to frequency domain as Fourier and Wavelet transforms, and its inverse transforms that allow reconstructing the original signal.

Automatic Classification of Impact–Echo Spectra II

INTRODUCTION

We study the application of artificial neural networks (ANNs) to the classification of spectra from impact-echo signals. In this paper we focus on analyses from experiments. Simulation results are covered in paper I.

Impact-echo is a procedure from Non-Destructive Evaluation where a material is excited by a hammer impact which produces a response from the material microstructure. This response is sensed by a set of transducers located on material surface. Measured signals contain backscattering from grain microstructure and information of flaws in the material inspected (Sansalone & Street, 1997). The physical phenomenon of impact-echo corresponds to wave propagation in solids. When a disturbance (stress or displacement) is applied suddenly at a point on the surface of a solid, such as by impact, the disturbance propagates through the solid as three different types of stress waves: a P-wave, an S-wave, and an R-wave. The P-wave is associated with the propagation of normal stress and the S-wave is associated with shear stress, both of them propagate into the solid along spherical wave fronts. In addition, a surface wave, or Rayleigh wave (R-wave) travels throughout a circular wave front along the material surface (Carino, 2001).

After a transient period where the first waves arrive, wave propagation becomes stationary in resonant modes of the material that vary depending on the defects inside the material. In defective materials propagated waves have to surround the defects and their energy decreases, and multiple reflections and diffraction with the defect borders become reflected waves (Sansalone, Carino, & Hsu, 1998). Depending on the observation time and the sampling frequency used in the experiments we may be interested in analyzing the transient or the stationary stage of the wave propagation in im-

pect-echo tests. Usually with high resolution in time, analyzes of wave propagation velocity can give useful information, for instance, to build a tomography of a material inspected from different locations. Considering the sampling frequency that we used in the experiments (100 kHz), a feature extracted from the signal as the wave propagation velocity is not accurate enough to discern between homogeneous and different kind of defective materials.

The data set for this research consists of sonic and ultrasonic impact-echo signal (1-27 kHz) spectra obtained from 84 parallelepiped-shape (7x5x22cm. width, height and length) lab specimens of aluminium alloy series 2000. These spectra, along with a categorization of the quality of materials among homogeneous, one-defect and multiple-defect classes were used to develop supervised neural network classifiers. We show that neural networks yield good classifications (<15% error) of the materials in four levels of classification detail as material condition, kind of defect, defect orientation and defect dimension. Results for Multilayer Perceptron (MLP) and Radial Basis Function (RBF) neural networks, Linear Discriminant Analysis (LDA), and k-Nearest Neighbours (kNN) algorithms (Duda, Hart, & Stork, 2000), (Bishop C.M., 2004) are presented. Figure 1 shows the scheme of categories proposed as a hierarchical layout with different levels of knowledge on the material defects (the percentage of success in classification is explained in Experimental Result section).

Figure 1. Classification tree with percentages of success in classification by RBF network. Numbers in brackets are results for simulations (paper I). General results are weighted by class probability since classes are not equally-probable.

BACKGROUND

The phenomenon of volumetric wave propagation in impact-eco can be modelled by means of the following two equations (Cheeke J.D., 2002),

$$\frac{\partial T_{ij}}{\partial x_j} = \rho_0 \frac{\partial^2 u_i}{\partial t^2} \quad (1)$$

$$T_{ij} = c_{ijkl} S_{kl} \quad (2)$$

where

ρ_0 : Material density.

u_i : Length elongation with respect to starting point in force direction.

$\frac{\partial T_{ij}}{\partial x_j}$: Force variation in i direction due to deformations in j directions.

c_{ijkl} : Elastic constant tensor (Hooke's law).

S_{kl}^i : Strain or relative volume change under deformation in face l in direction k in unitary cube that represents a material element.

Thus force variation in the direction i due to face stresses in j directions of the material elementary cube, is equal to the mass per volume (density) times the strain acceleration (Newton's third law in tensorial form). To

derive an analytical solution to problems that involve stress wave propagation in delimited solids is very complicated, so bibliography on this subject is not very extensive. Numeric models such as the Finite Element Method (FEM) can be used to obtain an approximation to the material theoretical response (Abraham O, Leonard C., Cote P., & Piwakowski B., 2000).

There are several studies that used the impact-echo signals in frequency domain to detect the existence of defects in materials (Sansalone et al., 1997), (Hill, McHung, & Turner, 2000), (Sansalone, Lin, & Street, 1998). It has been demonstrated that a sequence of tones and harmonics appears in the spectra, they are fundamental modes of propagation that travel inside the material (block-shape material) and its frequencies depend on the shape and size of the material inspected by impact-echo. According to the block face where a sensor is located, some or others fundamental modes are captured. However, other tones are formed by the reflections of the waves with the defects in the material, and their frequencies are related with the deepness of the flaws. In addition, the presence of defects causes shifting of the fundamental mode frequencies due to diffractions.

MLP neural network has been applied to impact-echo in mono-sensor configurations (using only one accelerometer) to detect flaws on concrete slabs (Pratt & Sansalone, 1992), identification of unilaterally working sublayer cracks (Stavroulakis, 1999), classification of concrete slabs in solid and defective (Xiang & Tso, 2002). Those applications used a few number of ex-

periments and many repetitions or combined simulated with experimental signals, so its results may be verified because of probable overfitting. Other application is to predict shallow crack depths in asphalt pavements using features from an extensive real signal dataset (Mei, 2004). Recently, we provided an application of MLP, RBF and LVQ to classification tree proposed here using temporal and frequency features extracted from the signals, finding that the better features were frequency features (Salazar, Uni6, Serrano, & Gosalbez, 2007).

In this paper we demonstrate the suitability of PCA application on the impact-echo signal spectra to obtain complex classifications in real experiments. The first components of PCA retain essentially all of the useful information and this compression optimally removes noise. The principal components represent sources of variance in the data. Thus the most significant spectra principal components show those features which vary the most between the spectra: it is important to realise that the principal components do not simply represent strong features. The principal components are eigenvectors of a symmetric matrix; they are simple rotations in the N -dimensional data space of the original axes on which the spectra are defined, thus they resemble the spectra (Bailer-Jones, 1996), (Bailer-Jones, Irwin, & Hippel, 1998), (Xu et al., 2004).

RECOGNITION OF DEFECT PATTERNS IN IMPACT-ECHO SPECTRA-EXPERIMENTS

Impact-Echo Signals

The equipment used in experiments was composed of: an instrumented hammer 084A14 PCB, 7 mono-axial accelerometers 353B17 PCB, a data acquisition module NI 6067E, a ICP signal conditioner F482A18 and a notebook for signal processing and control. The sample frequency in signal acquisition was 100,000 kHz, and observation time recorded was 30 ms. Figure 2a shows a photograph of the equipment employed in experiments, note that a 7x5x22cm. specimen with sensors positioned is being tested. Figure 2b shows a layout of the sensor locations on the surface of the piece (1 sensor at the back face, 4 sensors at the side faces, and 2 sensors at the top face), supports, and place of the impact. Sensors S4, S6, S8 are located at one third and S3, S5, S7 are located at two thirds of the piece length trough axis Z. S2 are in the middle of the opposite face to the impact.

The defects consisted in holes in the form of 10 mm. \varnothing cylinders, and cracks in the form of 5 mm. parallelepipeds with different orientations through the axes (X, Y) and planes (XY, ZY, XZ) of the material block. The dimensions of the defects were two: passing and half-passing through. Figure 2b shows a diagram of a defect of the class “half-passing trough crack oriented in plane ZY”. The complete set of defective materials analyzed is depicted in Figure 1.

Figure 2. Experimental setup and sensor configuration

2a. Equipment

2b. Sensor configuration layout

Feature Extraction and Selection

The methodology followed for feature extraction, feature selection, reduction of dimensionality and classification in the impact-echo signal spectra was the applied in Paper I. After signal acquisition a four-stage procedure was followed: feature extraction, dimensionality reduction, feature selection, and classification with ANNs.

In the feature extraction stage, a 1024-points FFT was applied to the measured signals and these spectra were compressed by PCA, selecting the first 20 components per each channel. Thus entries for the dimensionality reduction stage were 140 components (7channelsx20) for the 84 lab specimens. For each experiment (specimen) were performed around 22 repetitions, so the total of records was 1881 for experiments each one with 140 spectra components. In the dimensionality reduction stage PCA reduced the 140 spectra components to 50 spectra components with a 92% explained variance. This matrix of 50 selected components by 1881 records was the input for a feature selection process which objective was to found the “best” number of components for classification. Then various tests of classification using LDA and kNN varying the number of components from 5 to 50 by increments of 5 were applied. The components corresponding to the best percentage of success in classification with kNN and LDA were selected as entries for the stage of classification with MLP and RBF. The number of spectra components varied from 10 to 30 depending on the classification level. Parameters as spread for RBF, and the number of neurons in the hidden layer for MLP were tuned to obtain the best classification percentage of success of the ANNs.

All the classification used Leave-One-Out method. Repetitions of a piece in testing were not used in its training stage to avoid classifier to memorize the pieces instead of to generalize patterns. Table 1 shows summarised results for all the classifiers applied at the different levels of classification, these results refer to mean error in testing stage.

Experimental Results

General results of classifications for experiments in Table 1 show the RBF as the best classifier, improving its performance near to 20% with regard to simulation results in paper I at the more complex level of classification (12 classes). The percentage of classification success improved for every class at each level, particularly for multiple-defect class from 25% up to 92.6% at first level and 89.1% at fourth level, see Figure 1. In experiments, specimens with multiple-defects were prepared combining cracks and holes, so there was not much confusion with multiple-defect and one-defect classes.

Real experiments of impact-echo involved random variables in its execution, as the force injected in the impact excitation, and the position of the sensors that can vary from piece to piece due to they are manually controlled. Those variables yield repetitions of the experiments with its corresponding signal spectra that separate better class regions than Gaussian noise used to obtain replicates of the simulated model signals.

The results of experiment classifications confirm the feasibility of using neural networks for pattern recognition of defects in impact-echo signals. Table 2 contains the confusion matrix at level “defect orientation”. Homogeneous class is perfectly classified, and all the rest

Table 1. Summarised classification results for experiments

| | Error (%) | Level 1 (3 classes) | Level 2 (4 classes) | Level 3 (7 classes) | Level 4 (12 classes) |
|-------------|-----------|------------------------|------------------------|------------------------|-------------------------|
| Experiments | LDA-L | 7.8 | 18.3 | 28.5 | 39.6 |
| | LDA-Q | 6.7 | 15.3 | 20.8 | 26.3 |
| | LDA-M | 5.1 | 21 | 21.8 | 28.9 |
| | kNN | 3.3 | 14.2 | 20.5 | 23.2 |
| | MLP | 5.6 | 19.7 | 30.2 | 40.6 |
| | RBF | 1.75 | 10.88 | 10.99 | 11.93 |

Table 2. Confusion matrix obtained by RBF at experiments, level 3 of classification

| | Homogeneous | Hole X | Hole Y | Crack XY | Crack ZY | Crack XZ | Multiple defects |
|------------------|--------------|--------------|--------------|--------------|--------------|--------------|------------------|
| Homogeneous | 1,000 | 0,000 | 0,000 | 0,000 | 0,000 | 0,000 | 0,000 |
| Hole X | 0,000 | 0,914 | 0,000 | 0,000 | 0,048 | 0,000 | 0,038 |
| Hole Y | 0,000 | 0,000 | 0,488 | 0,107 | 0,298 | 0,107 | 0,000 |
| Crack XY | 0,000 | 0,000 | 0,022 | 0,909 | 0,009 | 0,025 | 0,034 |
| Crack ZY | 0,000 | 0,009 | 0,049 | 0,003 | 0,930 | 0,009 | 0,000 |
| Crack XZ | 0,000 | 0,000 | 0,005 | 0,003 | 0,044 | 0,949 | 0,000 |
| Multiple defects | 0,000 | 0,065 | 0,000 | 0,034 | 0,000 | 0,013 | 0,888 |

of six classes are well classified, except the “hole Y” class (48.8% success). This class is frequently confused with all the classes of cracks; it could be due to defect geometry does not allow produce a discernible wave pattern from propagation wave phenomena. In addition multiple-defect class is sometimes confused with cracks and hole X. It is due to particular patterns of one of the defects inside some multiple-defect specimens are more dominant in the spectra, causing multiple-defect spectra be alike to crack or hole Y spectra.

FUTURE TRENDS

The problem of material evaluation defined different levels of classification in a hierarchical outline with different kind of insight on quality of the tested material. It could be considered restate the problem to classify defects by ranges of defect size, independently of its shape or orientation, this kind of classification is very useful in industries as marble factories. The applicability of the proposed methodology has to be confirmed with application on different materials.

RBF neural network yielded good results for all levels of classification, but more algorithms have to be tested, taking into account the feasibility of its implementation in a real-time application and the improvement of the classification percentage of success. For instance, new algorithms of classification exploit linear dependencies in the data, and allow semi-supervised learning (Salazar, Vergara, Igual, Gosalbez, & Miralles, 2004), (Salazar, Vergara, Igual, & Gosalbez, 2005),

(Salazar, Vergara, Igual, & Serrano, 2007). That kind of modelling and learning procedure could be suitable for the classification of materials tested by impact-echo. Training stage and percentage of supervision is a critical subject in order to develop a suitable model from the data for classification. Thus depending on the kind of defective materials used in training a better adapted model for a specific classification would be defined. Then a decision fusion made by various classifiers could be more suitable than the decision made by one classifier.

CONCLUSION

We demonstrate the feasibility of using neural networks to extract patterns of different kinds of defects from impact-echo signal spectra in lab experiments. General results of the applied neural networks show RBF as the more suitable technique for the impact-echo problem even in complex levels of classifications, discerning up to 12 classes of homogeneous, one-defective and multiple-defect materials.

The proposed methodology has yield encouraging results with controlled lab experiments (same dimensions of the specimens, good-wave propagation material, and well-defined defects). The procedure has to be tested for processing real industry materials with a range of different dimensions, kind of defects and microstructures for which impact-echo signal spectra define fuzzy regions for classification.

KEY TERMS

Accelerometer: A device that measures acceleration which is converted into an electrical signal that is transmitted to signal acquisition equipment. In impact-echo testing, the measured acceleration refers to vibration displacements caused by the excitation of the short impact.

Dimensionality Reduction: A process to reduce the number of variables of a problem. Dimension of a problem is given by the number of variables (features or parameters) that represent the data. After signal feature extraction (that reduce the original signal sample

space), the dimensionality may be reduced more by feature selection methods.

Fast Fourier Transform (FFT): A class of algorithms used in digital signal processing to compute the Discrete Fourier Transform (DFT) and its inverse. It has the capability of taking functions from the time domain to the frequency domain. The frequency components obtained are the spectra of the signal.

Feature Extraction (FE): A process to map a multidimensional space into a space of fewer dimensions. In signal processing, instead of processing raw signals with thousands of samples is more efficient to process features extracted from the signals, such as, signal power, principal frequency, and attenuation coefficient.

Feature Selection (FS): A technique that selects a subset of features from a given set of features that represent the relevant properties of the data. FS also may be define as the task of choosing a small subset of features which is sufficient to predict the target labels well, is crucial for efficient learning. There are several FS methods based on margins (e.g., relief, simba) or information theory (e.g., infogain). Supervised FS methods use a priori knowledge on a classification variable, to select variables high correlated with the known variable.

Leave-One-Out: A method used in classification with the following steps: i.) Label the database cases with the known classes. ii.) Select a case of the database. iii.) Estimate the class for selected case by a classifier using the remaining cases as training data. iv.) Repeat steps ii and iii until the end of the cases. v.) Calculate the mean percentage of success for classification results.

Signal Conditioner (SC): A device that converts one type of electronic signal into another type of signal. Its primary use is to convert a signal that may be difficult to read by conventional instrumentation into a more easily read format. Typical SC functions are amplification, electrical isolation, and linearization.

AVI of Surface Flaws on Manufactures I

Girolamo Fornarelli

Politecnico di Bari, Italy

Antonio Giaquinto

Politecnico di Bari, Italy

INTRODUCTION

The defect detection on *manufactures* is of utmost importance in the optimization of industrial processes (Garcia 2005). In fact, the industrial *inspection* of engineering materials and products tends to the detection, localization and classification of *flaws* as quickly and as accurately as possible in order to improve the production quality. In this field a relevant area is constituted by visual *inspection*. Nowadays, this task is often carried out by a human expert. Nevertheless, such kind of *inspection* could reveal time-consuming and suffer of low repeatability because the judgment criteria can differ from operator to operator. Furthermore, visual fatigue or loss of concentration inevitably lead to missed defects (Han, Yue & Yu 1999, Kwak, Ventura & Tofang-Sazi 2000, Y.A. Karayiannis, R. Stojanovic, P. Mitropoulos, C.Koulamas, T. Stouraitis, S. Koubias & G. Papadopoulos 1999, Patil, Biradar & Jadhav 2005).

In order to reduce the burden of human testers and improve the detection of faulty products, recently many researchers have been engaged in developing systems in Automated Visual *Inspection* (AVI) of *manufactures* (Chang, Lin & Jeng 2005, Lei 2004, Yang, Pang & Yung 2004). These systems reveal easily reliable from technical point of view and mimic the experts in the evaluation process of defects appropriately (Bahlmann, Heidemann & Ritter 1999), even if defect detection in visual *inspection* can become a hard task. In fact, in industrial processes a large amount of data has to be handled and *flaws* belong to a great number of classes with dynamic defect populations, because defects could present similar characteristics among different classes and different interclass features (R. Stojanovic, P. Mitropoulos, C.Koullamas, Y. Karayiannis, S. Koubias & G. Papadopoulos 2001). Therefore, it is needed that visual *inspection* systems are able to adapt to dynamic operating conditions. To this purpose *soft computing*

techniques based on the use of Artificial Neural Networks (ANNs) have already been proposed in several different areas of industrial production. In fact, neural networks are often exploited for their ability to recognize a wide spread of different defects (Kumar 2003, Chang, Lin & Jeng 2005, Garcia 2005, Graham, Maas, Donaldson & Carr 2004, Acciani, Brunetti & Fornarelli 2006). Although adequate in many instances, in other cases Neural Networks cannot represent the most suitable solution. In fact, the design of ANNs often requires the extraction of parameters and features, during a *preprocessing* stage, from a suitable data set, in which the most possible defects are recognized (Bahlmann, Heidemann & Ritter 1999, Karras 2003, Rimac-Drlje, Keller & Hocenski 2005). Therefore, methods based on neural networks could be time expensive for in-line applications because such preliminary steps and could reveal complex (Kumar 2003, Kwak, Ventura & Tofang-Sazi 2000, Patil, Biradar & Jadhav 2005, R. Stojanovic, P. Mitropoulos, C.Koullamas, Y. Karayiannis, S. Koubias & G. Papadopoulos 2001). For this reason, when in an industrial process time constraints play an important role, a hardware solution of the abovementioned methods can be proposed (R. Stojanovic, P. Mitropoulos, C.Koullamas, Y. Karayiannis, S. Koubias & G. Papadopoulos 2001), but such kind of solution implies a further design effort which can be avoided by considering Cellular Neural Networks (CNNs) (Chua & Roska 2002).

Cellular Neural Networks have good potentiality to overcome this problem, in fact their hardware implementation and massive parallelism can satisfy urgent time constraints of some industrial processes, allowing the inclusion of the diagnosis inside the production process. In this way the defect detection method could enable to work in *real time* according to the specific industrial process.

BACKGROUND

Cellular Neural Networks consist of processing units $C(i, j)$, which are arranged in an $M \times N$ grid, as shown in Figure 1.

The generic basic unit $C(i, j)$ is called cell: it corresponds to a first-order nonlinear circuit, electrically connected to the cells, which belong to the set $S_r(i, j)$, named *sphere of influence of the radius r* of $C(i, j)$. Such set $S_r(i, j)$ is defined as:

$$S_r(i, j) = \left\{ C(k, l) \mid \max_{1 \leq k \leq M, 1 \leq l \leq N} (|k - i|, |l - j|) \leq r \right\}$$

An $M \times N$ Cellular Neural Network is defined by an $M \times N$ rectangular array of cells $C(i, j)$ located at site (i, j) , $i = 1, 2, \dots, M$, $j = 1, 2, \dots, N$. Each cell $C(i, j)$ is defined mathematically by the following state and output equations:

$$\begin{cases} \frac{dx_{ij}}{dt} = -x_{ij} + \sum_{C(k, l) \in S_r(i, j)} A(i, j; k, l) y_{kl} + \sum_{C(k, l) \in S_r(i, j)} B(i, j; k, l) u_{kl} + z_{ij} \\ y_{ij} = \frac{1}{2} (|x_{ij} + 1| - |x_{ij} - 1|) \end{cases}$$

where $x_{ij} \in \mathbb{R}$, $y_{ij} \in \mathbb{R}$ and $z_{ij} \in \mathbb{R}$ are state, output and threshold of cell $C(i, j)$, $y_{kl} \in \mathbb{R}$, and $u_{kl} \in \mathbb{R}$ are output and input of cell $C(k, l)$, respectively. $A(i, j; k, l)$ and

$B(i, j; k, l)$ are called the *feedback* and the *input synaptic operators* and uniquely identify the network.

The reported circuit model constitutes a hardware paradigm which allows fast processing of signals. For this reason, in the past CNNs were considered as an useful framework for defect detection in industrial applications (Roska 1992). Successively different CNN-based contributions working in *real time* and aiming at the defect detection in the industrial field have been proposed (Bertucco, Fargione, Nunnari & Risitano 2000), (Occhipinti, Spoto, Branciforte & Doddo 2001), (Guinea, Gordaliza, Vicente & García-Alegre 2000), (Perfetti & Terzoli 2000). In (Bertucco, Fargione, Nunnari & Risitano 2000) and (Occhipinti, Spoto, Branciforte & Doddo 2001) non-destructive control of mechanical parts in aeronautical industrial production is carried out defining an algorithm which is implemented by means of CNNs entirely. These methods reveal effective, but a complex acquisition system is required to provide information about the defectiveness. In (Guinea, Gordaliza, Vicente & García-Alegre 2000) CNNs constitute the core processors of a system which realizes an automatic *inspection* of metal laminates, whereas in (Perfetti & Terzoli 2000) two CNN-based algorithms are proposed in order to detect stains and irregularities in a textile application. In both works real-time is guaranteed, but in (Guinea, Gordaliza, Vicente & García-Alegre 2000) synthesis criteria of CNN circuit parameters could reveal difficult to satisfy, whereas in (Perfetti & Terzoli 2000) such criteria are not defined.

In the following section a CNN-based method, that enables to overcome the most of drawbacks which arise in the reported approaches, is proposed.

Figure 1. Standard CNN architecture

AUTOMATIC DEFECT DETECTION METHOD

In this section an automatic method for the visual *inspection* of surface *flaws* of *manufactures* is proposed. This method is realized by means of a CNN-based architecture, which will be accurately described in the companion chapter (Fornarelli & Giaquinto 2007).

The suggested approach consists of three steps. The first one realizes a *preprocessing* stage which enables to identify eventual defected areas; in the second stage the matching between such pre-processed image and a *reference image* is performed; finally, in the third

step an output binary image, in which only defects are represented, is yielded.

The proposed solution needs not complex acquisition system neither feature extraction, in fact the image is directly processed and the synthesis parameters of the system are evaluated from the statistical image properties automatically. Furthermore, the proposed system is well suited for single board implementation.

The scheme that represents the proposed method is shown in Figure 2.

As it can be observed, it is formed by three modules: a *Preprocessing* module, an Image Matching module and a Defect Detection one. The input images, named **O** and **R**, are acquired by means of a camera, which yields 256-gray levels images, whose dimensions are $m \times n$. The image **O** represents the *manufacture* under test or a part of it. Such image contains the Region of Interest (ROI), that is the specific region of an object, in which defects are to be detected.

The image **R** constitutes a *reference image*, in which a product without defects (or its part) is depicted. Such image is stored in a memory and acquired off-line during the phase of system calibration. It is used to detect possible variations caused by the presence of dents, scratches or breakings on an observed surface. In order to allow a good match between the *reference image* and the under test one, the *preprocessing* blocks realize a *contrast enhancement*, providing images **O_F** and **R_F**, that constitute the inputs for the subsequent

Image Matching module. The target of this block is finding the minimum difference between the two images **O_F** and **R_F**. In fact, during the production process, the acquiring system could give images in which the *manufacture* is shifted according the four cardinal directions. This implies that the difference between **O_F** and **R_F** could lead to the detection of false defects. The Image Matching Module minimizes such effects, looking for the best matching between the image to be processed and the reference one. Successively the difference image **D** feeds the Defect Detection module. This part aims at the detection of the presence of *flaws* on the product under test and gives an output image containing only the defects. The output image allows to activate alarming systems able to detect the presence of *flaws*, making this industrial task easier, in fact it could support experts in their diagnoses. The detailed implementation of each module will be illustrated in the second part of this contribution.

FUTURE TRENDS

In order to provide the most information related to defects detected by the proposed approach in industrial processes, features of *flaws* should be identified. For this reason, future works will be devoted to the evaluation of different characteristics like dimension of defects, kind of damage and its degree. Moreover, the advantages by applying the proposed method in various industrial fields will be investigated and techniques minimizing eventual misclassifications in particular applications, will be developed.

CONCLUSION

In this chapter a CNN-based method for the visual *inspection* of surface *flaws* of *manufactures* has been proposed. The approach consists of three modules: a *Preprocessing* Module provides images, in which contrast is enhanced. An Image Matching Module allows to make up for eventual misalignment between the *manufacture* under test and the acquisition system. Finally, the Defect Detection Module enables to extract images which contain defects of *manufactures*.

The suggested method offers attractive advantages. It reveals general, therefore it can be introduced in different industrial fields, in which the identification

Figure 2. Block diagram of the proposed CNN-based method

of superficial anomalies like dents, corrosions or spots on *manufactures* is a fundamental task.

Moreover, the suggested method is finalized to the implementation by means of an architecture, entirely formed by Cellular Neural Networks, exploiting the potentialities that this kind of network offers in processing signals. Therefore, the proposed approach enables to automate in line diagnosis processes reducing operators' burden in identifying production defects.

KEY TERMS

Artificial Neural Networks: A set of basic processing units which communicate to each other by weighted connections. These units give rise to a parallel processing with particular properties such as the ability to adapt or learn, to generalise, to cluster or organise data, to approximate non-linear functions. Each unit receives an input from neighbours or external sources and uses it to compute an output signal. Such signal is propagated to other units or is a component of the network output. In order to map an input set into an output one a neural network is trained by teaching patterns, changing its weights according to proper learning rules.

Automated Visual Inspection: An automatic form of quality control normally achieved using one or more cameras connected to a processing unit. Automated Visual Inspection has been applied to a wide range of products. Its target consists of minimizing the effects of visual fatigue of human operators who perform the defect detection in a production line environment.

Cellular Neural Networks: A particular circuit architecture which possesses some key features of Artificial Neural Networks. Its processing units are arranged in an $M \times N$ grid. The basic unit of Cellular Neural Networks is called cell and contains linear and non linear circuit elements. Each cell is connected only to its neighbour cells. The adjacent cells can interact directly with each other, whereas cells not directly connected together may affect each other indirectly because of the propagation effects of the continuous time dynamics.

Defect Detection: Extraction of information about the presence of an instance in which a requirement is not satisfied in industrial processes. The aim of Defect Detection consists of highlighting manufactures which are incorrect or missing functionality or specifications.

Image Matching: Establishment of the correspondence between each pair of visible homologous image points on a given pair of images, aiming at the evaluation of novelties.

Industrial Inspection: Analysis pursuing the prevention of unsatisfactory industrial products from reaching the customer, particularly in situations where failed manufactures can cause injury or even endanger life.

Region of Interest: A selected subset of samples within a dataset identified for a particular purpose. In image processing, the Region of Interest is identified by the boundaries of an object. The encoding of a Region of Interest can be achieved by basing its choice on: (a) a value that may or may not be outside the normal range of occurring values; (b) purely separated graphic information, like drawing elements; (c) separated semantic information, such as a set of spatial and/or temporal coordinates.

AVI of Surface Flaws on Manufactures II

INTRODUCTION

Automatic visual inspection takes a relevant place in *defect detection* of industrial *production*. In this field a fundamental role is played by methods for the detection of superficial anomalies on manufactures.

In particular, several systems have been proposed in order to reduce the burden of human operators, avoiding the drawbacks due to the subjectivity of judgement criteria (Kwak, Ventura & Tofang-Sazi 2000, Patil, Biradar & Jadhav 2005).

Proposed solutions are required to be able to handle and process a large amount of data. For this reason, neural networks-based methods have been suggested for their ability to deal with a wide spread of data (Kumar 2003, Chang, Lin & Jeng 2005, Garcia 2005, Graham, Maas, Donaldson & Carr 2004, Acciani, Brunetti & Fornarelli 2006). Moreover, in many cases these methods must satisfy time constraints of industrial processes, because the inclusion of the diagnosis inside the *production* process is needed.

To this purpose, architectures, based on Cellular Neural Networks (CNNs), revealed successful in the field of *real time defect detection*, due to the fact that these networks guarantee a hardware *implementation* and massive parallelism (Bertuccio, Fargione, Nunnari & Risitano 2000), (Occhipinti, Spoto, Branciforte & Doddo 2001), (Perfetti & Terzoli 2000). On the basis of these considerations, a method to identify superficial damages and anomalies in manufactures has been given in (Fornarelli & Giaquinto 2007). This method is aimed at the *implementation* by means of an architecture entirely formed by Cellular Neural Networks, whose synthesis is illustrated in the present work. The suggested solution reveals effective for the detection of defects, as shown by two test cases carried out on an injection pump and a sample textile.

BACKGROUND

In the companion paper an approach for *defect detection* of surface flaws on manufactures is proposed: this approach can be divided into three modules, named Preprocessing module, Image Matching module and *Defect Detection* module, respectively. The first one realizes a pre-processing stage which enables to identify eventual defected areas; in the second stage the *matching* between such pre-processed image and a reference one is performed; finally, in the third step an output binary image, in which only defects are represented, is yielded.

The proposed solution needs not complex acquisition system neither feature extraction, in fact the image is directly processed and the synthesis parameters of the networks are evaluated from the statistical image properties automatically. Furthermore, the proposed system is well suited for a single board *implementation*.

CNN-BASED DIAGNOSIS ARCHITECTURE

The detailed *implementation* of each module will be illustrated in the following. Successively the results obtained by testing the suggested architecture on two real cases are shown and a discussion of numerical outcomes is reported.

Preprocessing Module

The Preprocessing is realized by a *Fuzzy Contrast Enhancement* block. This block consists of a *Fuzzy Associative Memory* (FAM), developed as the preprocessing stage of the CNN-based system considered in (Carnimeo & Giaquinto 2002). The proposed circuit enables to transform 256-gray levels images into fuzzified ones, whose contrast is enhanced, due to the fact

that their *histograms* are stretched. To this purpose a proper fuzzification procedure is developed to define two *fuzzy* subsets adequate to describe the semantic content of patterns such as images of industrial objects, which can be classified as belonging to the **Object/Background** class.

In an analogous way, the domain of output values has been characterized by means of two output *fuzzy* subsets defined as **Dark** and **Light**. In particular, the *fuzzy* rules which provide the mapping from original images (**O/R**) into fuzzified ones (**O_F/R_F**) can be expressed as:

IF $O(i, j) \in \mathbf{Object}$ THEN $O_F(i, j) \in \mathbf{Dark}$
 IF $O(i, j) \in \mathbf{Background}$ THEN $O_F(i, j) \in \mathbf{Light}$

where $O(i, j)$ and $O_F(i, j)$ denote the gray level value of the (i, j) -th pixel in the original image and in the fuzzified one, respectively. As showed in (Carnimeo & Giaquinto 2002), the reported *fuzzy* rules can be encoded into a single FAM.

Then, a Cellular Neural Network is synthesized to behave as the codified FAM by adopting the synthesis procedure developed in (Carnimeo & Giaquinto 2002), where the synthesis of a CNN-based memory, which contains the abovementioned fuzzification rules is accurately formulated.

Contrasted images present a stretched *histogram*. This implies that such operation minimizes the effects of image noise, caused by environmental problems like dust or dirtiness of camera lenses. Moreover, it reduces the undesired information due to the combination between the non uniformity of the illumination in the image and the texture of the manufacture (Jamil, Bakar, Mohd, & Sembok 2004).

Image Matching Module

In Figure 1 the block diagram corresponding to the Image Matching module is reported. The target of this module consists of finding the best *matching* between the images yielded by processing the acquired image and the reference one. To this purpose the image **O_F** is shifted by one pixel into the four cardinal directions (NORTH; SOUTH, EAST and WEST), using four space-invariant CNNs (T. Roska, L. Kek, L. Nemes, A. Zarandy & P. Szolgay 1999) and obtaining the images **O_{FN}**, **O_{FS}**, **O_{FE}** and **O_{FW}**. Successively the switch

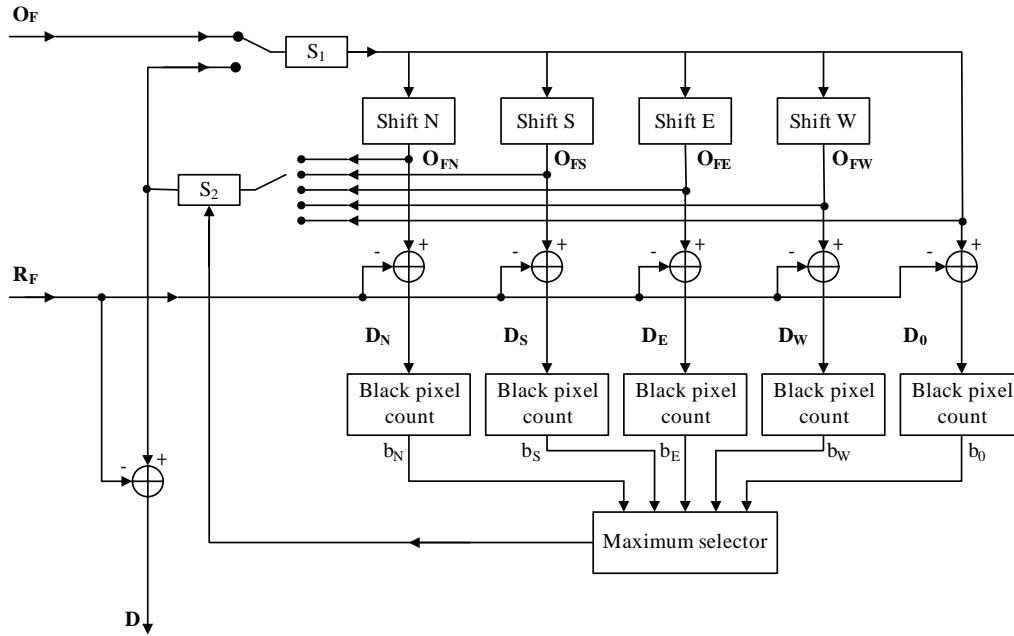

S_1 changes its position, excluding the image **O_F**. The reference image **R_F** is subtracted by the images **O_{FN}**, **O_{FS}**, **O_{FE}** and **O_{FW}**, then the number b_N , b_S , b_E , b_W and b_0 of black pixels in the resulting images **D_N**, **D_S**, **D_E**, **D_W** and **D₀** are computed. The image, which best matches with the reference one, presents the maximum numbers of black pixels. Therefore, such value drives the switch S_2 , which allows to feedback the image that best matches with the reference one. In this way the image which presents the minimum difference becomes the input for a successive computational step. The processing is repeated until **D₀** presents the best *matching*. When this condition is satisfied, the difference image **D** between **D₀** and **R_F** is computed. As it can be noticed the operations needed for each directional shift can be carried on simultaneously, reducing the computational time at each step.

Defect Detection Module

The third part of the suggested architecture is a *Defect Detection* module. The subsystem is synthesized with the aim of computing the output binary image **F**, in which only the defects are present. Such module is composed by the sequence of a Major Voting circuit, a CNN associative memory for *contrast enhancement* and a Threshold circuit. The corresponding CNN-based *implementation* is obtained by considering space invariant networks.

In detail the Major Voting circuit minimizes the number of false detections caused by the presence of noise, highlighting the dents or those flaws which lead to a changing in the reflectance of light in the original image. The output of the Major Voting block **D_M** feeds a CNN working as the associative memory described in the previous Preprocessing module subsection. This operation provides an output image **D_{MF}** whose *histogram* is bimodal. In this kind of image the selection of a threshold, which highlights the defects, results feasible. In fact, a proper value is given by the mean of the modes of the *histogram*. Then, this image is segmented by means of the corresponding space-invariant CNN (T. Roska, L. Kek, L. Nemes, A. Zarandy & P. Szolgay 1999), obtaining the corresponding binary image **F**. In this way errors corresponding to incorrect identification of defects are minimized because only flaws are visible after the *segmentation*.

Figure 1. Block diagram corresponding to the Image Matching module

Numerical Examples

The capabilities of the designed CNN-based architecture have been investigated on images representing the central part of injection pumps containing the Region of Interest (ROI), that is the flange, like the reported in Figure 2(a), whose *histogram* is shown in Figure 2(b). As it can be observed, this image presents two dents on the left and the bottom of the observed region. Dents are due to the collisions that can occur when pumps are moved among the different *production* locations during the various stages of the mounting. This image and the reference one are firstly processed by a circuit based on two (4×4)-cell CNNs described in the previous subsection. In Figures 3(a-b) the corresponding output image yielded by the synthesized CNNs and its *histogram* are shown. It can be noticed that contrast is highly enhanced and the *histogram* is stretched.

In figure 4(a) the output **D** of the Image Matching module is reported: impulsive-like noise due to the shifting or the imperfect lighting of the image or the reflection due to dirtiness is still present at this step.

Finally, **D** feeds the *Defect Detection* module: in Figures 4(b) and 4(c) the output of Major Voting block **D_M** and the final image **F** are shown, respectively. As it can be observed in image **D_M**, the effects of irregular lighting or changing in reflections due to the dust or

dirtiness are minimized. The results are encouraging, in fact the designed cellular system provides an output image (see Figure 4(c)), in which the areas of the manufacture with defects are well visible and detected by white pixels.

Performances of the proposed system have been tested by means of a second experiment carried out on a sample textile. This industrial field has been investigated because time constraints of an automated *defect detection* system in the textile industry are of crucial importance (R. Stojanovic, P. Mitropulos, C.Koullamas, Y. Karayiannis, S. Koubias & G.Papadopoulos 2001).

In Figure 5 (a) the acquired image of the textile is reported. In this case the whole image of the manufacture coincides with the ROI. It can be noted that a bright vertical thin bar compares in the middle of the image. It corresponds to a lacked stamp. In the reported example the identification of defects constitutes a non trivial problem. In fact, the stamped areas have variegated geometric shapes, which can be depicted with a great number of different gray levels. The previously reported method has been applied to detect such kind of defects, yielding an image in which the only defect (the thin bar) is represented, similarly to the test case reporting dents of injection pumps. In Figure 5(b)-(c)-(d) the corresponding outputs of the Preprocessing module, the Image *Matching* module and the *Defect*

Figure 2. (a) Acquired Image containing the ROI (the flange of injection pump) with two dents; (b) gray-scale histogram of the image in Figure 2(a)

(b)

Figure 3. (a) Output image of the Fuzzy Contrast Enhancement module fed by the image in Figure 2(a); (b) gray-scale histogram of the image in Figure 3(a)

(a)

(b)

Detection one are shown, respectively. It can be noticed that the central defect has been isolated effectively, even if a percentage of the areas to be identified is missed. This is due to the fact that, when details need to be detected, it is required that contrast is maximum. Nevertheless, as the contrast is increased, the histogram of the resulting image is emphasized toward extreme values of gray levels with respect to the acquired image. This implies that, due to a saturation phenomenon,

an information loss about details takes place. (Brendel & Roska 2002).

Finally, in the output image small white areas are misclassified as defects. This problem rises from the shift of the manufacture respect to the acquisition system. The Image Matching module minimizes the effects of such problem, but it can not delete them completely when mechanical deformations of the manufacture occur as in the textile field. As it is shown in Figure 5(d),

Figure 4. (a) Output of the image matching module; (b) output of the major voting block in the defect detection module; (c) output image containing the detected defects, represented by white pixels

Figure 5. (a) Acquired image of a textile containing a thin bar, (b) corresponding output of the fuzzy contrast enhancement module, (c) output of the image matching module, (d) final output image

this implies the presence of false positives, which will be investigated subsequently.

FUTURE TRENDS

As it can be argued from an observation of obtained numerical results, future works will be devoted to a more detailed analysis of misclassifications. In particular,

false positives could be analyzed by means of further techniques which relate the characteristics of the possible defected zones and the ones containing effective defects according to the constraints of the application. For instance, in the reported numerical examples the false positives have geometric sizes which are negligible if compared to the areas of eventual flaws. Therefore, a control of area dimensions could enable to discriminate the two kinds of regions.

CONCLUSION

In this paper a CNN-based architecture for the visual inspection of surface flaws of manufactures has been proposed. The architecture consists of modules, which are entirely realized by well-established circuit networks. The reported design approach offers some interesting advantages. The proposed solution needs nor complex acquisition system neither feature extraction, in fact images are directly processed and the synthesis parameters, like thresholds for image *segmentation*, are evaluated from the statistical image properties automatically. Furthermore, due to the possible hardware *implementation* of CNNs the resulting system can satisfy urgent time constraints relating to the in-line detection of some industrial productive processes, allowing the inclusion of the diagnosis inside the *production* steps.

KEY TERMS

Automated Visual Inspection: An automatic form of quality control normally achieved using one or more cameras connected to a processing unit. Automated Visual Inspection has been applied to a wide range of products. Its target consists of minimizing the effects of visual fatigue of human operators who perform the defect detection in a production line environment.

Cellular Neural Networks: A particular circuit architecture which possesses some key features of Artificial Neural Networks. Its processing units are arranged in an $M \times N$ grid. The basic unit of Cellular Neural Networks is called cell and contains linear and non linear circuit elements. Each cell is connected only to its neighbour cells. The adjacent cells can interact directly with each other, whereas cells not directly connected together may affect each other indirectly because of the propagation effects of the continuous time dynamics.

Fuzzy Associative Memory: A kind of content-addressable memory in which the recall occurs correctly if input data fall within a specified window consisting of an upper bound and a lower bound of the stored patterns. A Fuzzy Associative Memory is identified by a matrix of fuzzy values. It allows to map an input fuzzy set into an output fuzzy one.

Histogram Stretching: A point process that involves the application of an appropriate transformation function to every pixel of a digital image in order to

redistribute the information of the histogram toward the extremes of a grey level range. The target of this operation consists of enhancing the contrast of digital images.

Image Matching: Establishment of the correspondence between each pair of visible homologous image points on a given pair of images, aiming at the evaluation of novelties.

Major Voting: An operation aiming at deciding whether the neighbourhood of a pixel in a digital image contains more black or white pixels, or their number is equal. This effect is realized in two steps. The first one gives rise to an image, where the sign of the rightmost pixel corresponds to the dominant colour. During the second step the grey levels of the rightmost pixels are driven into black or white values, depending on the dominant colour, or they are left unchanged otherwise.

Real Time System: A system that must satisfy explicit bounded response time constraints to avoid failure. Equivalently, a real-time system is one whose logical correctness is based both on the correctness of the outputs and its timeliness. The timeliness constraints or deadlines are generally a reflection of the underlying physical process being controlled.

Region of Interest: A selected subset of samples within a dataset identified for a particular purpose. In image processing, the Region of Interest is identified by the boundaries of an object. The encoding of a Region of Interest can be achieved by basing its choice on: (a) a value that may or may not be outside the normal range of occurring values; (b) purely separated graphic information, like drawing elements; (c) separated semantic information, such as a set of spatial and/or temporal coordinates.

Basic Cellular Neural Networks Image Processing

University of Extremadura, Badajoz, Spain

INTRODUCTION

Since its seminal publication in 1988, the Cellular Neural Network (CNN) (Chua & Yang, 1988) paradigm have attracted research community's attention, mainly because of its ability for integrating complex computing processes into compact, real-time programmable analogic VLSI circuits (Rodríguez *et al.*, 2004).

Unlike cellular automata, the CNN model hosts nonlinear processors which, from analogic array inputs, in continuous time, generate analogic array outputs using a simple, repetitive scheme controlled by just a few real-valued parameters. CNN is the core of the revolutionary Analogic Cellular Computer, a programmable system whose structure is the so-called CNN Universal Machine (CNN-UM) (Roska & Chua, 1993). Analogic CNN computers mimic the anatomy and physiology of many sensory and processing organs with the additional capability of data and program storing (Chua & Roska, 2002).

This article reviews the main features of this Artificial Neural Network (ANN) model and focuses on its outstanding and more exploited engineering application: Digital Image Processing (DIP).

BACKGROUND

In the following paragraphs, a definition of the parameters and structure of the CNN is performed in order to clarify the practical usage of the model in DIP.

The standard CNN architecture consists of an $M \times N$ rectangular array of cells $C(i, j)$ with Cartesian coordinates (i, j) , $i = 1, 2, \dots, M$, $j = 1, 2, \dots, N$. Each cell or neuron $C(i, j)$ is bounded to a connected neighbourhood or sphere of influence $S_r(i, j)$ of positive integer radius r , which is the set of all neighbouring cells satisfying the following property:

$$S_r(i, j) = \left\{ C(k, l) \mid \max_{1 \leq k \leq M, 1 \leq l \leq N} \{ |k - i|, |l - j| \} \leq r \right\} \quad (1)$$

This set is sometimes referred as a $(2r+1) \times (2r+1)$ neighbourhood, e.g., for a 3×3 neighbourhood, r should be 1. Thus, the parameter r controls the connectivity of a cell, i.e. the number of active synapses that connects the cell with its immediate neighbours.

When $r > N/2$ and $M = N$, a fully connected CNN is obtained, where every neuron is connected to every other cell in the network and $S_r(i, j)$ is the entire array. This extreme case corresponds to the classic Hopfield ANN model (Chua & Roska, 2002).

The state equation of any cell $C(i, j)$ in the $M \times N$ array structure of the standard CNN may be described mathematically by:

$$C \frac{dz_{ij}(t)}{dt} = -\frac{1}{R} z_{ij}(t) + \sum_{C(k, l) \in S_r(i, j)} [A(i, j; k, l) \cdot y_{kl}(t) + B(i, j; k, l) \cdot x_{kl}] + I_{ij} \quad (2)$$

where C and R are values that control the transient response of the neuron circuit (just like an RC filter, typically set to unity for the sake of simplicity), I is generally a constant value that biases or thresholds the state matrix $Z = \{z_{ij}\}$, and S_r is the local neighbourhood of cell $C(i, j)$ defined in (1), which controls the influence of the input data $X = \{x_{ij}\}$ and the network output $Y = \{y_{ij}\}$ for time t .

This means that both input and output planes interact with the state of a cell through the definition of a set of real-valued weights, $A(i, j; k, l)$ and $B(i, j; k, l)$, whose size is determined by the neighbourhood radius r . The matrices or cloning templates A and B are called the feedback and feed-forward (or control) operators, respectively.

A standard CNN is typically defined with constant values for r , I , A and B , thus implying that for a fixed input image X , a neuron $C(i, j)$ is provided for each

pixel (i, j) , with constant weighted circuits defined by the feedback template A that connects the cell with the output plane Y , and by the control template B , which connects the neuron to the neighbouring pixels of input $x_{ij} \in X$. The value of the neuron state z_{ij} is then adjusted with the bias parameter I , and passed as input to a piecewise-linear function in order to determine the output value y_{ij} . This function may be expressed as

$$y_{ij} = \frac{1}{2} \left(\left| z_{ij}(t) + 1 \right| - \left| z_{ij}(t) - 1 \right| \right) \quad (3)$$

In the Image Processing context, a grey-scale image input X can be represented pixel-wise using a linear map between a pixel value (e.g. a 8-bit integer luminance matrix with 256 grey-scale levels) and the CNN input interval $[-1, +1]$, where the lower limit is used to implement full luminance (i.e. white) and the upper for black pixels (Chua & Yang, 1988).

BASIC CNN IMAGE PROCESSING

The main application of the CNN model, due to its convolution-like scheme, has been DIP modelling and design. In the next subsections a number of basic DIP approaches are introduced, underlining the importance of the network parameters by giving illustrative examples of application. Starting from the standard model described in the previous section, the definition of the standard isotropic CNN follows. Then, an example of application in logic DIP processing is performed in order to introduce the nonlinear effects that implies the using a non-zero feedback template.

The Isotropic CNN Model

For a still image, X will be invariant with time, and for video, $X = X(t)$. In the most general case, r , A , B and I may vary with position and time, and the cloning templates are defined as nonlinear, with the possibility of integrating inhibitory signals for the state matrix and even nonlinear templates that interact with mixed input-output-state data (Chua & Roska, 2002).

These possible extensions raise the definition of a special (and simpler) class of CNN, called isotropic or space-invariant, in which r , A , B and I are fixed for the whole network and where linear synaptic operators are utilized.

In other words,

$$\sum_{C(k,l) \in S_r(i,j)} A(i,j;k,l) \cdot y_{kl} = \sum_{|k-l| \leq r} \sum_{|l-j| \leq r} A(i-k, j-l) \cdot y_{kl}$$

$$\sum_{C(k,l) \in S_r(i,j)} B(i,j;k,l) \cdot x_{kl} = \sum_{|k-l| \leq r} \sum_{|l-j| \leq r} B(i-k, j-l) \cdot x_{kl}$$

$$\text{and } I_{ij} = I. \quad (4)$$

The vast majority of the templates defined in the template compendium of (Chua & Roska, 2002) for the CNN-UM are based on this isotropic scheme, using $r = 1$, and binary images in the input plane.

If no feedback (i.e. $A = 0$) is used, then the CNN behaves as a convolution network, using B as a spatial filter, I as a threshold and the piecewise linear output (3) as a limiter or saturated output filter. In this way, virtually any spatial filter from DIP theory (Jain, 1989) can be implemented on such a feed-forward driven CNN, which ensures its output stability.

For instance, the EDGE template defined by

$$A = 0, B_{EDGE} = \begin{bmatrix} -1 & -1 & -1 \\ -1 & 8 & -1 \\ -1 & -1 & -1 \end{bmatrix}, I = -1 \quad (5)$$

is designed to work correctly for binary inputs, giving black (+1) output pixels in the input locations where a black edge pixel exists (i.e. if a black pixel has 1 white neighbour), and white (-1) pixels elsewhere.

However, when a grey-scale input image is fed to this CNN, the output may not be a binary image. To solve this potential problem, the following modification is performed over the EDGE CNN:

$$A = 2, B = B_{EDGE}, I = -0.5 \quad (6)$$

The definition of a centre feedback absolute value greater than 1 in (6) ensures a binary output and thus output network stability. The B template used in these CNN is of the *Laplacian* type, having the important property that all surrounding input synaptic weights are inhibitory (i.e. negative) and identical, but the centre synaptic weight is excitatory, and the average of all input synaptic weights is zero.

Apart from edges, convex corners (i.e. black pixels with at least five white neighbours) may also be detected with the following modification of its parameters:

$$A = 2, B = B_{EDGE}, I = -8.5 \quad (7)$$

This example illustrates the important role played by the threshold parameter I . This parameter may be viewed as a bias index that reallocates the origin z_0 of the output function (3) (Fernández *et al.*, 2006).

Basic Logic Operators

In order to perform pixel-wise logic operations between two binary images X_1 and X_2 , the initial state $Z(0)$ of the network is also utilized as a variable (Chua & Roska, 2002). In standard feed-forward driven CNN, this variable $Z(0)$ is usually set to zero but it can also be used in order to obtain results valid for another applications, such as motion detection and estimation (Torralba & Hérault, 1999).

For example, for a binary set union (logic OR), the following templates are defined:

$$X = X_1, B_1, Z(0) = X_2, A = 3, B = 3, I = 2 \quad (8)$$

whereas for set intersection (logic AND), these variables are defined as

$$X = X_1, Z(0) = X_2, A = 1.5, B = 1.5, I = -1.5 \quad (9)$$

Once again, the usage of excitatory feedback ensures output stability through the saturation output function (3), and the threshold properly biases the final result.

Feedback-Driven Standard CNN

The feedback templates used in all the previously exemplified CNN utilize (if any) only the central element of the template. A standard CNN with off-centre nonzero feedback elements is a special class that exhibits more complex dynamics than those treated so far (Chua & Roska, 1993).

The use of a centre element in A , $a_{00} > 1$, means that the output will be binary, i.e. network output will never be stable in the linear region of the saturation function (3) (Chua & Roska, 2002). With this restriction, if another element is set in the feedback template,

then two possible situations may occur: the activation of cells in the opposite part of only one of the saturation regions (partial inversion), or wave propagating cell inversions in both binary states.

The first kind of these feedback-driven CNN is said to have the mono-activation property if cells in only one saturated region can enter the linear region. Thus, if cells can enter the linear region from the positive saturation region, then those cells saturated in the negative part must fulfil that the overall contribution of A , B and I in its sphere of influence S_r must be less than -1 . That is,

$$w_{ij}(t) = \sum_{S_r(i,j)} [a_{kl} \cdot y_{kl}(t) + b_{kl} \cdot x_{kl}] + I_{ij} < -1 \quad (10)$$

On the other hand, if cells enter the linear region only from the negative saturation region, then the contribution for positive stable cells must be $w_{ij}(t) > 1$. It can be demonstrated that in a mono-activated CNN with positive A coefficients, with $a_{00} > 1$ and saturated initial values, all the cells that enter the linear region change monotonically their state from (only) one saturated area to the other, and therefore it is a stable nonlinear network (Chua & Roska, 2002).

If, for instance, one element in A is negative, the transient will not be monotonic, which does not necessarily imply network instability. An example of a non-monotonic but stable CNN is the Connected Component Detector (CCD) (Matsumoto *et al.*, 1990 a) whose templates (for the horizontal case) are the following:

$$A_{CCD} = \begin{bmatrix} 0 & 0 & 0 \\ 1 & 2 & -1 \\ 0 & 0 & 0 \end{bmatrix}, B = 0, I = 0 \quad (11)$$

For designing a unidirectional wave propagating mono-activated CNN, a binary activation pattern is defined, which will trigger the transient until output stability is reached (Chua & Roska, 2002). An example of this type of stable feedback-driven CNN is the (horizontal) Shadow Detector (Matsumoto *et al.*, 1990 b) whose parameters are:

$$A_{Shadow} = \begin{bmatrix} 0 & 0 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & 0 \end{bmatrix}, B = 0, I = 0 \quad (12)$$

FUTURE TRENDS

There is a continuous quest by engineers and specialists: compete with and imitate nature, especially some “smart” animals. Vision is one particular area which computer engineers are interested in. In this context, the so-called Bionic Eye (Werblin *et al.*, 1995) embedded in the CNN-UM architecture is ideal for implementing many spatio-temporal neuromorphic models.

With its powerful image processing toolbox and a compact VLSI implementation (Rodríguez *et al.*, 2004), the CNN-UM can be used to program or mimic different models of retinas and even combinations of them (Lázár *et al.*, 2004). Moreover, it can combine biologically based models, biologically inspired models, and analogic artificial image processing algorithms. This combination will surely bring a broader kind of applications and developments.

CONCLUSION

A number of other advances in the definition and characterization of CNN have been researched in the past decade. This includes the definition of methods for designing and implementing larger than 3×3 neighbourhoods in the CNN-UM (Kék & Zarándy, 1998), the efficient implementation of halftoning techniques (Crounse *et al.*, 1993), the CNN implementation of some image compression techniques (Venetianer *et al.*, 1995) or the design of a CNN-based Fast Fourier Transform algorithm over analogic signals (Perko *et al.*, 1998), between many others. Some of them have also been described in this book in the article entitled *Advanced Cellular Neural Networks Image Processing*.

In this article, a general review of the main properties and features of the Cellular Neural Network model has been addressed, focusing on its DIP capabilities from a basic viewpoint. CNN is now a fundamental and powerful toolkit for real-time nonlinear image processing tasks, mainly due to its versatile programmability, which has powered its hardware development for visual sensing applications.

KEY TERMS

Artificial Neural Network (ANN): A system made up of interconnecting artificial neurons or nodes (usually simplified neurons) which may share some properties of biological neural networks. They may either be used to gain an understanding of biological neural networks, or for solving traditional artificial intelligence tasks without necessarily attempting to model a real biological system. Well known examples of ANN are the Hopfield, Kohonen and Cellular (CNN) models.

Feedback: The signal that is looped back to control a system within itself. When the output of the system is fed back as a part of the system input, it is called a feedback loop. A simple electronic device which is based on feedback is the electronic oscillator. The Phase-Locked Loop (PLL) is an example of complex feedback system.

Neuromorphic: A term coined by Carver Mead in the late 1980s to describe VLSI systems containing electronic analogue circuits that mimic neuro-biological architectures present in the nervous system. More recently, its definition has been extended to include both analogue, digital and mixed mode A/D VLSI systems that implements models of neural systems as well as software algorithms.

Piecewise Linear Function: A function $f(x)$ that can be split into a number of linear segments, each of which is defined for a non-overlapping interval of x .

Spatial Convolution: A term used to identify the linear combination of a series of discrete 2D data (a digital image) with a few coefficients or weights. In the Fourier theory, a convolution in space is equivalent to (spatial) frequency filtering.

Template: Also known as kernel, or convolution kernel, is the set of coefficients used to perform a spatial filter operation over a digital image via the spatial convolution operator.

Transient: In electronics, a transient system is a short life oscillation in a system caused by a sudden change of voltage, current, or load. They are mostly found as the result of the operation of switches. The signal produced by the transient process is called the transient signal or simply the transient. Also, the transient of a dynamic system can be viewed as its path to a stable final output.

VLSI: Acronym that stands for Very Large Scale Integration. It is the process of creating integrated circuits by combining thousands (nowadays hundreds of millions) of transistor-based circuits into a single chip. A typical VLSI device is the microprocessor.

Bayesian Neural Networks for Image Restoration

Radu Mutihac

University of Bucharest, Romania

INTRODUCTION

Numerical methods commonly employed to convert experimental data into interpretable images and spectra commonly rely on straightforward transforms, such as the Fourier transform (FT), or quite elaborated emerging classes of transforms, like wavelets (Meyer, 1993; Mallat, 2000), wedgelets (Donoho, 1996), ridgelets (Candes, 1998), and so forth. Yet experimental data are incomplete and noisy due to the limiting constraints of digital data recording and the finite acquisition time. The pitfall of most transforms is that imperfect data are directly transferred into the transform domain along with the signals of interest. The traditional approach to data processing in the transform domain is to ignore any imperfections in data, set to zero any unmeasured data points, and then proceed as if data were perfect.

Contrarily, the maximum entropy (ME) principle needs to proceed from frequency domain to space (time) domain. The ME techniques are used in data analysis mostly to reconstruct positive distributions, such as images and spectra, from blurred, noisy, and/or corrupted data. The ME methods may be developed on axiomatic foundations based on the probability calculus that has a special status as the only internally consistent language of inference (Skilling 1989; Daniell 1994). Within its framework, positive distributions ought to be assigned probabilities derived from their entropy.

Bayesian statistics provides a unifying and self-consistent framework for data modeling. Bayesian modeling deals naturally with uncertainty in data explained by marginalization in predictions of other variables. Data overfitting and poor generalization are alleviated by incorporating the principle of Occam's razor, which controls model complexity and set the preference for simple models (MacKay, 1992). Bayesian inference satisfies the likelihood principle (Berger, 1985) in the sense that inferences depend only on the probabilities assigned to data that were measured and not on the properties of some admissible data that had never been acquired.

Artificial neural networks (ANNs) can be conceptualized as highly flexible multivariate regression and multiclass classification non-linear models. However, over-flexible ANNs may discover non-existent correlations in data. Bayesian decision theory provides means to infer how flexible a model is warranted by data and suppresses the tendency to assess spurious structure in data. Any probabilistic treatment of images depends on the knowledge of the point spread function (PSF) of the imaging equipment, and the assumptions on noise, image statistics, and prior knowledge. Contrarily, the neural approach only requires relevant training examples where true scenes are known, irrespective of our inability or bias to express prior distributions. Trained ANNs are much faster image restoration means, especially in the case of strong implicit priors in the data, nonlinearity, and nonstationarity. The most remarkable work in Bayesian neural modeling was carried out by MacKay (1992, 2003) and Neal (1994, 1996), who theoretically set up the framework of Bayesian learning for adaptive models.

BACKGROUND

Bayesian approach to image restoration is based on the assumption that all of the relevant image information may be stated in probabilistic terms and prior probabilities are known. The ME principle is optimally setting prior probabilities for positive additive distributions. Yet Bayes' theorem and the ME principle share one common future: the updating of a state of knowledge. In some cases, running Bayes' theorem in one hypothesis space and applying the ME principle in another lead to similar calculations.

Neuromorphic and Bayesian modeling may apparently look like extremes of the data modeling spectrum. ANNs are non-linear parallel computational devices endowed with gradient descent algorithms trained by example to solve prediction and classification problems. In contrast, Bayesian statistics is based on coherent

inference and clear axioms. Yet both approaches aim to create models in agreement with data. Bayesian decision theory provides intrinsic means to model ranking. Bayesian inference for ANNs can be implemented numerically by deterministic methods involving Gaussian approximations (MacKay, 1992), or by Monte-Carlo methods (Neal, 1996). Two features distinguish the Bayesian approach to learning models from data. First, beliefs derived from background knowledge are used to select a prior probability distribution for model parameters. Secondly, predictions of future observations are performed by integrating the model's predictions with respect to the posterior parameter distribution obtained by updating this prior with new data. Both aspects are difficult in neural modeling: the prior over network parameters has no obvious relation to prior knowledge, and integration over the posterior is computationally demanding. The properties of priors can be elucidated by defining classes of prior distributions for net parameters that reach sensible limits as the net size goes to infinity (Neal, 1994). The problem of integrating over the posterior can be solved using Markov chain Monte Carlo (Neal 1996).

Bayesian Image Modeling

The fundamental concept of Bayesian analysis is that the plausibility of alternative hypotheses $\{H_i\}_{i \in \mathbb{N}}$ is represented by probabilities $\{P_i\}_{i \in \mathbb{N}}$, and inference is performed by evaluating these probabilities. Inference may operate on various propositions related in neural modeling to different paradigms. Bayes' theorem makes no reference to any sample or hypothesis space, neither it determines the numerical value of any probability directly from available information. As a prerequisite to apply Bayes' theorem, a principle to cast available information into numerical values is needed.

In statistical restoration of gray-level digital images, the basic assumption is that there exists a scene adequately represented by an orderly array of N pixels. The task is to infer reliable statistical descriptions of images, which are gray-scale digitized pictures and stored as an array of integers representing the intensity of gray level in each pixel. Then the shape of any positive, additive image can be directly identified with a probability distribution. The image is conceived as an outcome of a random vector $\mathbf{f} = \{f_1, f_2, \dots, f_N\}$, given in the form

of a positive, additive probability density function.

Likewise, the measured data $\mathbf{g} = \{g_1, g_2, \dots, g_M\}$ are expressed in the form of a probability distribution (Fig. 1). Further assumption refers to image data as a linear function of physical intensity, and that the errors (noise) \mathbf{b} is data independent, additive, and Gaussian with zero mean and known standard deviation σ_m , $m = 1, 2, \dots, M$ in each pixel. The concept of image entropy and the entropy alternative expressions used in image restoration are discussed by Gull and Skilling (1985). A brief review of different approaches based on ME principle, as well as a full Bayesian approach for solving inverse problems are due to Djafari (1995).

Image models are derived on the basis of intuitive ideas and observations of real images, and have to comply with certain criteria of invariance, that is, operations on images should not affect their likelihood. Each model comprises a hypothesis H with some free parameters $\mathbf{w} = (\alpha, \beta, \dots)$ that assign a probability density $P(\mathbf{f} / \mathbf{w}, H)$ over the entire image space and normalized to integrate to unity. Prior beliefs about the validity of H before data acquisition are embedded in $P(H)$. Extreme choices for $P(H)$ only may exceed the evidence $P(\mathbf{f} / H)$, thus the plausibility $P(H / \mathbf{f})$ of H is given essentially by the evidence $P(\mathbf{f} / H)$ of the image \mathbf{f} . Consequently, objective means for comparing various hypotheses exist.

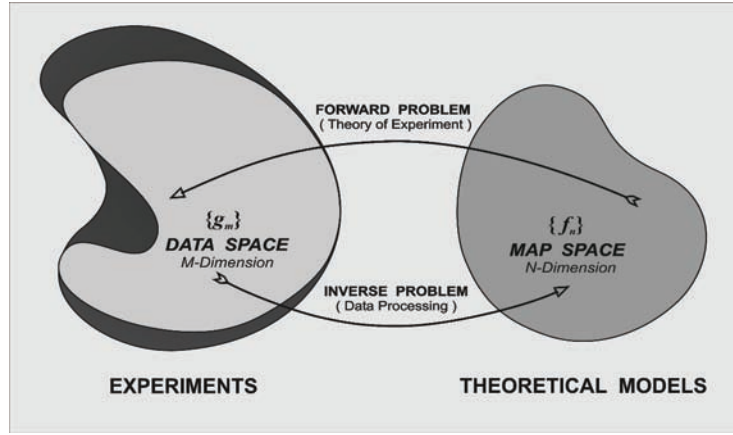

Initially, the free parameters \mathbf{w} are either unknown or they are assigned very wide prior distributions. The task is to search for the best fit parameter set \mathbf{w}_{MP} , which has the largest likelihood given the image. Following Bayes' theorem:

$$P(\mathbf{w} / \mathbf{f}, H) = \frac{P(\mathbf{f} / \mathbf{w}, H) \cdot P(\mathbf{w} / H)}{P(\mathbf{f} / H)} \quad (1)$$

where $P(\mathbf{f} / \mathbf{w}, H)$ is the likelihood of the image \mathbf{f} given \mathbf{w} , $P(\mathbf{w} / H)$ is the *prior* distribution of \mathbf{w} , and $P(\mathbf{f} / H)$ is the evidence for H . A prior $P(\mathbf{w} / H)$ has to be assigned quite subjectively based on our beliefs about images. Since $P(\mathbf{w} / \mathbf{f}, H)$ is normalized to 1, then the denominator in (1) ought to satisfy

$$P(\mathbf{f} / H) = \int_{\mathbf{w}} P(\mathbf{f} / \mathbf{w}, H) \cdot P(\mathbf{w} / H) \cdot d\mathbf{w} .$$
 The inte-

Figure 1. Flowchart summarizing the forward and inverse problems

grant is often dominated by the likelihood in w_{MP} , so that the evidence of H is approximated by the best fit

likelihood $P(f/w_{MP}, H)$ times the Occam's factor (MacKay, 1992):

$$P(f/H) \cong P(f/w_{MP}, H) \cdot P(w_{MP}/H) \cdot \Delta w \quad (2)$$

Assuming uniform prior parameter distributions $P(w/H)$ over all admissible parameter sets, then

$$P(w_{MP}) = \frac{1}{\Delta_0 w}, \text{ and the evidence becomes:}$$

$$P(f/H) \cong P(f/w_{MP}, H) \cdot \frac{\Delta w}{\Delta_0 w} \quad (3)$$

The ratio

$$\frac{\Delta w}{\Delta_0 w}$$

between the posterior accessible volume of the model's parameter space and the prior accessible volume prevents data overfitting by favoring simpler models. Further, Bayes' theorem gives the probability of H up to a constant:

$$P(H/f) \propto P(f/H) \cdot P(H) \quad (4)$$

Maximum Entropy Methods

Applying the ME principle amounts to assigning a distribution $\{P_1, P_2, \dots, P_n\}$ on some hypothesis space by the criterion that it shall maximize some form of entropy subject to constraints that express properties we wish the distribution to have, but are not sufficient to determine it. The ME methods require specifying in advance a definite hypothesis space which sets down the possibilities to be taken into consideration. They come out with a probability distribution, rather than a probability. The ME probability of a single hypothesis H that is not embedded in a space of alternative hypotheses does not make any sense. The ME methods do not require for input the numerical values of any probabilities on that space, rather they assign numerical values to available information as expressed by the choice of hypothesis space and constraints.

LINEAR IMAGING EXPERIMENTS

In the widely spread linear case, where the N -dimensional image vector f consists of the pixel values of an unobserved image, and the M -dimensional data vector g is made of the pixel values of an observed image supposed to be a degraded version of f , and assuming zero-mean Gaussian additive errors:

$$\mathbf{g} = \mathbf{R} \mathbf{f} + \mathbf{b} \quad (5)$$

where the $M \times N$ matrix \mathbf{R} stands for the PSF (transfer function or instrumental response) of the imaging system; then the likelihood of data is:

$$P(\mathbf{g} / \mathbf{f}, \mathbf{C}, H) = \frac{1}{(2\pi)^{\frac{M}{2}} \cdot \det^{\frac{1}{2}} \mathbf{C}} \cdot \exp \left(-\frac{1}{2} (\mathbf{g} - \mathbf{f})^T \mathbf{C}^{-1} (\mathbf{g} - \mathbf{f}) \right) \quad (6)$$

where \mathbf{C} is the covariance matrix of the error vector \mathbf{b} . If there is no correlation among the pixels and each pixel has the standard deviation σ_m , $m=1, 2, \dots, M$, then the symmetric full rank covariance matrix becomes diagonal with the elements $C_{mm} = \sigma_m^2$, $m=1, 2, \dots, M$. Hence the probability of the data \mathbf{g} given the image \mathbf{f} may be written as:

$$P(\mathbf{g} / \mathbf{f}, \mathbf{C}, H) = \frac{1}{(2\pi)^{\frac{M}{2}} \prod_{m=1}^M \sigma_m} \cdot \exp \left(-\frac{1}{2} \sum_{m=1}^M \frac{\left(g_m - \sum_{n=1}^N R_{mn} f_n \right)^2}{\sigma_m^2} \right) \quad (7)$$

The full joint posterior $P(\mathbf{f}, \theta / \mathbf{g}, H)$ of the image \mathbf{f} and the unknown PSF parameters denoted generically by θ should be evaluated. Then the required inference about the posterior probability $P(\mathbf{f} / \mathbf{g}, H)$ is obtained as a marginal integral of this joint posterior over the uncertainties in the PSF:

$$P(\mathbf{f} / \mathbf{g}, H) = \int P(\mathbf{f}, \theta / \mathbf{g}, H) \cdot d\theta = \int P(\mathbf{f} / \theta, \mathbf{g}, H) \cdot P(\theta / \mathbf{g}, H) \cdot d\theta \quad (8)$$

Now applying Bayes' theorem for the parameters θ :

$$P(\theta / \mathbf{g}, H) = \frac{P(\mathbf{g} / \theta, H) \cdot P(\theta / H)}{P(\mathbf{g} / H)} \quad (9)$$

and substituting in (8)

$$\int P(\mathbf{f}, \theta / \mathbf{g}, H) \cdot d\theta \propto \int P(\mathbf{f} / \theta, \mathbf{g}, H) \cdot P(\mathbf{g} / \theta, H) \cdot P(\theta / H) \cdot d\theta \quad (10)$$

If the evidence $P(\mathbf{g} / \theta, H)$ is sharply peaked around some value $\hat{\theta}$ and the prior $P(\theta / H)$ is fairly flat in that region, then $P(\mathbf{f} / \mathbf{g}, H) \cong P(\mathbf{f} / \hat{\theta}, \mathbf{g}, H)$. Otherwise, if the marginal integrant is not well approximated at the modal value of the evidence, then misleading narrow posterior probability densities may result.

If the errors have uniform standard deviation σ_b , then the symmetric covariance matrix has full rank M with $\mathbf{C} = \sigma_b^2 \mathbf{I}$, and the probability of data (7) becomes:

$$P(\mathbf{g} / \mathbf{f}, \beta, H) = \frac{1}{Z_b(\beta)} \cdot \exp \left(-\sum_{m=1}^M \beta \cdot E_b(\mathbf{g} / \mathbf{f}, H) \right) \quad (11)$$

where $\beta = 1/\sigma_b^2$ is a measure of the noise in each pixel,

$$E_b(\mathbf{g} / \mathbf{f}, H) = \frac{1}{2} \cdot \frac{\mathbf{b}^T \mathbf{b}}{\sigma_b^2} = \frac{1}{2} \sum_{m=1}^M \frac{\left(g_m - \sum_{n=1}^N R_{mn} f_n \right)^2}{\sigma_b^2}$$

is the error function, and Z_b is the noise partition function.

More complex models use the intrinsic correlation function $\mathbf{C} = [\mathbf{G} \mathbf{G}^T]^{-1}$, where \mathbf{G} is a convolution from an imaginary hidden image, which is uncorrelated, to the real correlated image.

If the prior probability of the image \mathbf{f} is also Gaussian:

$$P(\mathbf{f} / \mathbf{F}_0, H) = \frac{1}{(2\pi)^{\frac{N}{2}} \cdot \det^{\frac{1}{2}} \mathbf{F}_0} \cdot \exp \left(-\frac{1}{2} \mathbf{f}^T \mathbf{F}_0^{-1} \mathbf{f} \right) \quad (12)$$

where \mathbf{F}_0 is the prior covariance matrix of \mathbf{f} , and assuming a uniform standard deviation of the image, then its prior probability distribution becomes:

$$P(\mathbf{f} / \alpha, H) = \frac{1}{Z_f(\alpha)} \cdot \exp \left(-\alpha E_f(\mathbf{f} / \mathbf{F}_0) \right) \quad (13)$$

where the parameter $\alpha = 1/\sigma_f^2$ measures the expected smoothness of \mathbf{f} , $Z_f(\alpha) = (2\pi/\alpha)^{N/2}$ is the partition

function of f , and

$$E_f(f / \mathbf{F}_0) = \frac{1}{2} f^T \mathbf{F}_0^{-1} f.$$

The posterior probability of image f given data g is derived from Bayes' theorem:

$$P(f / g, \alpha, \beta, H) = \frac{P(g / f, \beta, H) \cdot P(f / \alpha, H)}{P(g / \alpha, \beta, H)} \quad (14)$$

where the evidence $P(g / \alpha, \beta, H)$ is the normalizing factor. Since the denominator in (14) is a product of Gaussian functions of f , we may rewrite:

$$P(f / g, \alpha, \beta, H) = \frac{\exp(-\alpha E_f - \beta E_b)}{Z_M(\alpha, \beta)} = \frac{\exp(-M(f))}{Z_M(\alpha, \beta)} \quad (15)$$

where

$$M(f) = \alpha E_f + \beta E_b$$

and $Z_M(\alpha, \beta) = \int_f \exp(-M(f)) df$

with the integral covering the space of all admissible images in the partition function. Therefore, minimizing the objective function $M(f)$ corresponds to finding the most probable image f_{MP} , which is the mean value of the Gaussian posterior distribution. Its covariance matrix \mathbf{A}^{-1} that defines the joint error bars on f can be obtained from the Hessian matrix $\mathbf{A} = -\nabla \nabla \log P(f / g, \alpha, \beta, H)$ evaluated at f_{MP} . The image f_{MP} is obtained by differentiating $\log P(f / g, \alpha, \beta, H)$ and solving for the derivative being zero:

$$f_{MP} = \left[\mathbf{R}^T \mathbf{R} - \frac{\sigma_b^2}{\sigma_f^2} \mathbf{C} \right]^{-1} \mathbf{R}^T f \quad (16)$$

The term

$$\frac{\sigma_b^2}{\sigma_f^2} \mathbf{C}$$

regularizes the ill-conditioned inversability. When the term

$$\frac{\sigma_b^2}{\sigma_f^2} \mathbf{C}$$

is negligible, the optimal linear filter

$$\left[\mathbf{R}^T \mathbf{R} - \frac{\sigma_b^2}{\sigma_f^2} \mathbf{C} \right]^{-1} \mathbf{R}^T$$

equates to the pseudoinverse $\mathbf{R}^{-1} = [\mathbf{R}^T \mathbf{R}]^{-1} \mathbf{R}^T$.

Entropic Prior of Images

Invoking the ME principle requires that the prior knowledge to be stated as a set of constraints on f , though affecting the amount by which the image reconstruction is offset from reality. The prior information about f may be expressed as a probability distribution (Djafari, 1995):

$$P(f / \alpha, H) = \frac{1}{Z(\alpha)} \cdot \exp(-\alpha \cdot \Phi(f)) \quad (17)$$

where α is generally a positive parameter and $Z(\alpha)$ is the normalizing factor. The entropic prior in the discrete case may correspond to potential functions like:

$$\Phi(f) = \sum_{n=1}^N f_n \cdot \ln \frac{f_n}{U} \quad (18)$$

where U is the total number of quanta in the image f (Mutihac *et al.*, 1997).

The posterior probability of an image f drawn from some measured data g is given by Bayes' theorem:

$$P(f / g, \alpha, \mathbf{C}, H) \propto \exp \left(-\alpha \sum_{n=1}^N f_n \cdot \ln \left(\frac{f_n}{U} \right) \right) \cdot \exp \left(-\frac{1}{2} \sum_{m=1}^M \frac{\left(g_m - \sum_{n=1}^N R_{mn} f_n \right)^2}{\sigma_m^2} \right) \quad (19)$$

An estimation rule, such as posterior mean or maximum a posteriori (MAP), is needed in order to choose an optimal, unique, and stable solution \tilde{f} for the estimated image. The posterior probability is assumed to summarize the full state of knowledge on a given scene. Producing a single image as the best restoration naturally leads to the most likely one which maximizes the posterior probability $P(f / g, \alpha, \mathbf{C}, H)$,

along with some statement of reliability derived from the spread of all admissible images.

In variational problems with linear constraints, Agmon *et al.* (1979) showed that the potential function associated to a positive, additive image is always concave for any set of Lagrange multipliers, and it possesses an unique minimum which coincides with the solution of the nonlinear system of constraints. As a prerequisite, the linear independence of the constraints is checked and then the necessary and sufficient conditions for a feasible solution are formulated. Wilczek and Drapatz (1985) suggested the Newton-Raphson's iteration method as offering high accuracy results. Ortega and Rheinboldt (1970) adopted a continuation technique for the very few cases where the Newton's method fails to converge. These techniques are nevertheless successful in practice for relatively small data sets only and assume a symmetric positive definite Hessian matrix of the potential function.

Quality Assessment of Image Restoration

In all digital imaging systems, quality degradation is inevitably due to various sources like photon shot noise, finite acquisition time, readout noise, dark current noise, and quantization noise. Some noise sources can be effectively suppressed yet some cannot. The combined effect of these degradation sources is often modeled by Gaussian additive noise (Pham *et al.* 2005).

In order to quantitatively estimate the restoration quality in the case of similar size ($M = N$) for both the measured \mathbf{g} and the restored image $\tilde{\mathbf{f}}$, the mean energy of restoration error:

$$D = \frac{1}{N} \sum_{n=1}^N [g_n - \tilde{f}_n]^2 \quad (20)$$

may be used as a merit factor. Yet too high a value for D may set the restored image quite away from the original scene and raise questions on introducing spurious features for which there is no clear evidence in measurements and complicating the subsequent inference and plausibility.

A more realistic degradation measure of image blurring by additive noise is referred to in terms of a metric

called blurred signal-to-noise ratio redefined here by using the noise variance in each pixel such as:

$$BSNR = 10 \cdot \lg \frac{1}{N} \sum_{n=1}^N \frac{[y_n - \bar{y}_n]^2}{\sigma_n^2} \quad (21)$$

where $\mathbf{y} = \mathbf{g} - \mathbf{b}$ is the difference between the measured data \mathbf{g} and the noise \mathbf{b} .

In simulations, where the original image \mathbf{f} of the measured data \mathbf{g} is available, the objectivity of testing the performance of image restoration algorithms may be assessed by the improvement of signal-to-noise ratio metric defined as:

$$ISNR = 10 \cdot \lg \frac{\sum_{n=1}^N [f_n - g_n]^2}{\sum_{n=1}^N [f_n - \tilde{f}_n]^2} \quad (22)$$

where $\tilde{\mathbf{f}}$ is the best statistical estimation of the correct solution \mathbf{f} .

While mean squared error metrics like ISNR do not always reflect the perceptual properties of the human visual system, they may provide an objective standard by which to compare different image processing techniques. Nevertheless, it is of major significance that various algorithms behavior be analyzed from the point of view of ringing and noise amplification, which can be a key indicator of improvement in quality for subjective comparisons of restoration algorithms (Banham and Katsaggelos, 1997).

FUTURE TRENDS

A practical Bayesian framework for neural-inspired modeling aims to develop probabilistic models that fit data and perform optimal predictions. The link between Bayesian inference and neural models gives new perspectives to the assumptions and approximations made on ANNs when used as associative memories. Evolutionary optimization algorithms capable to discover absolute function minimum (maximum) are needed.

A statistically biased redefinition of the concept of pattern existence used in a quantitative manner to assess the overall quality of digital images with domain-specific relevance would increase the accuracy of ranking the image restoration methods.

An efficient MAP procedure has to be implemented in a recursive supervised trained neural net to get restored (reconstructed) the best image in compliance with the existing constraints, measuring and modeling errors.

CONCLUSION

A major intrinsic difficulty in Bayesian image restoration resides in determination of a prior law for images. The ME principle solves this problem in a self-consistent way. The ME model for image deconvolution enforces the restored image to be positive. The spurious negative areas and complementary spurious positive areas are wiped off and the dynamic range of the restored image is substantially enhanced.

Image restoration based on image entropy is effective even in the presence of significant noise, missing or corrupted data. This is due to the appropriate regularization of the inverse problem of image restoration introduced in a coherent way by the ME principle. It satisfies all consistency requirements when combining the prior knowledge and the information contained in experimental data. A major result is that no artifacts are added since no structure is enforced by entropic priors.

Bayesian ME approach is a statistical method which directly operates in spatial domain, thus eliminating the inherent errors coming out from numerical Fourier direct and inverse transformations and from the truncation of signals.

KEY TERMS

Artificial Neural Networks (ANNs): Highly parallel nets of interconnected simple computational elements, which perform elementary operations like summing the incoming inputs (afferent signals) and amplifying/thresholding the sum.

Bayesian Inference: An approach to statistics in which all forms of uncertainty are expressed in terms of probability.

Deconvolution: An algorithmic method for eliminating noise and improving the resolution of digital data by reversing the effects of convolution on recorded data.

Digital Image: A representation of a 2D/3D image as a finite set of digital values called pixels/voxels typically stored in computer memory as a raster image or raster map.

Entropy: A measure of the uncertainty associated with a random variable. Entropy quantifies information in a piece of data.

Image Restoration: A blurred image can be significantly improved by deconvolving its PSF in such a way that the result is a sharper and more detailed image.

Point Spread Function (PSF): The output of the imaging system for an input point source.

Probabilistic Inference: An effective approach to approximate reasoning and empirical learning in AI.

Behaviour-Based Clustering of Neural Networks

INTRODUCTION

The field of off-line optical character recognition (OCR) has been a topic of intensive research for many years (Bozinovic, 1989; Bunke, 2003; Plamondon, 2000; Toselli, 2004). One of the first steps in the classical architecture of a text recognizer is preprocessing, where noise reduction and normalization take place. Many systems do not require a binarization step, so the images are maintained in gray-level quality. Document enhancement not only influences the overall performance of OCR systems, but it can also significantly improve document readability for human readers. In many cases, the noise of document images is heterogeneous, and a technique fitted for one type of noise may not be valid for the overall set of documents. One possible solution to this problem is to use several filters or techniques and to provide a classifier to select the appropriate one.

Neural networks have been used for document enhancement (see (Egmont-Petersen, 2002) for a review of image processing with neural networks). One advantage of neural network filters for image enhancement and denoising is that a different neural filter can be automatically trained for each type of noise.

This work proposes the clustering of neural network filters to avoid having to label training data and to reduce the number of filters needed by the enhancement system. An agglomerative hierarchical clustering algorithm of supervised classifiers is proposed to do this. The technique has been applied to filter out the background noise from an office (coffee stains and footprints on documents, folded sheets with degraded printed text, etc.).

BACKGROUND

Multilayer Perceptrons (MLPs) have been used in previous works for image restoration: the input to the MLP is the pixels in a moving window, and the output is the restored value of the current pixel (Egmont-Petersen, 2000; Hidalgo, 2005; Stubberud, 1995; Suzuki, 2003). We have also used neural network filters to estimate the gray level of one pixel at a time (Hidalgo, 2005): the input to the MLP consisted of a square of pixels that was centered at the pixel to be cleaned, and there were four output units to gain resolution (see Figure 1). Given a set of noisy images and their corresponding clean counterparts, a neural network was trained. With the trained network, the entire image was cleaned by scanning all the pixels with the MLP. The MLP, therefore, functions like a nonlinear convolution kernel. The universal approximation property of a MLP guarantees the capability of the neural network to approximate any continuous mapping (Bishop, 1996).

This approach clearly outperforms other classic spatial filters for reducing or eliminating noise from images (the mean filter, the median filter, and the closing/opening filter (Gonzalez, 1993)) when applied to enhance and clean a homogeneous background noise (Hidalgo, 2005).

BEHAVIOUR-BASED CLUSTERING OF NEURAL NETWORKS

Agglomerative Hierarchical Clustering

Agglomerative hierarchical clustering is considered to be a more convenient approach than other clustering

Figure 1. An example of document enhancement with an artificial neural network. A cleaned image (right) is obtained by scanning the entire noisy image (left) with the neural network.

algorithms, mainly because it makes very few assumptions about the data (Jain, 1999; Mollineda, 2000). Instead of looking for a single partition (based on finding a local minimum), this clustering algorithm constructs a hierarchical structure by iteratively merging clusters according to certain dissimilarity measure, starting from singletons until no further merging is possible (one general cluster). The hierarchical clustering process can be illustrated with a tree that is called dendrogram, which shows how the samples are merged and the degree of dissimilarity of each union (see Figure 2). The dendrogram can be easily broken at a given level to obtain clusters of the desired cardinality or with a specific dissimilarity measure. A general hierarchical clustering algorithm can be informally described as follows:

1. Initialization: M singletons as M clusters.
2. Compute the dissimilarity distances between every pair of clusters.
3. Iterative process:

- a) Determine the closest pair of clusters i and j .
 - b) Merge the two closest clusters into a new cluster $i+j$.
 - c) Update the dissimilarity distances from the new cluster $i+j$ to all the other clusters.
 - d) If more than one cluster remains, go to step a).
4. Select the number N of clusters for a given criterion.

Behaviour-Based Clustering of Supervised Classifiers

When the points of the set to be clustered are supervised classifiers, both a dissimilarity distance and the way to merge two classifiers must be defined (see Figure 2):

1. The dissimilarity distance between two clusters can be based on the behaviour of the classifiers with respect to a validation dataset. The more similar the output of two classifiers is, the closer they are.
2. To merge the closest pair of clusters, a new classifier is trained with the associated training data

Figure 2. Behaviour-based clustering of supervised classifiers. An example of the dendrogram obtained for $M=5$ points: A, B, C, D, E. If $N=3$, three clusters are selected: A+B, C, D+E. In this work, to merge two clusters, a new classifiers is trained. For example, cluster D+E is trained with the data used to train the classifiers D and E.

of both clusters. Another possibility is to build an ensemble of the two classifiers.

An Application of Behaviour-based Clustering of MLPs to Document Enhancement

In this work, MLPs are used as supervised classifiers. When two clusters are merged, a new MLP is trained with the associated training data of the two merged MLPs.

This behaviour-based clustering algorithm has been applied to enhance printed documents with typical noises from an office (folded sheets, wrinkled sheets, coffee stains, ...). Figure 1 shows an example of a noisy printed document (wrinkled sheet) from the corpus.

A set of MLPs is trained as neural filters for different types of noise and then clustered into groups to obtain a reduced set of neural clustered filters. In order to automatically determine which clustered filter is the most suitable to clean and enhance a real noisy image, an image classifier is also trained using MLPs. Experimental results using this enhancement system show excellent results in cleaning noisy documents (Zamora-Martínez, 2007).

FUTURE TRENDS

Document enhancement is becoming more and more relevant due to the huge amount of scanned documents. Besides, it not only influences the overall performance of **OCR** systems, but it can also significantly improve document readability for human readers.

The method proposed in this work can be improved twofold: by using ensembles of MLPs when two MLPs are merged, and by improving the method to select the neural clustered filter that is the most suitable to enhance a given noisy image.

CONCLUSION

An agglomerative hierarchical clustering of supervised-learning classifiers that uses a measure of similarity among classifiers based on their behaviour on a validation dataset has been proposed. As an application of this clustering procedure, we have designed an enhancement system for document images using neural network filters. Both objective and subjective evaluations of the cleaning method show excellent results in cleaning noisy documents. This method could also be used to clean and restore other types of images, such as noisy backgrounds in scanned documents, stained paper of historical documents, vehicle license recognition, etc.

KEY TERMS

Artificial Neural Network: An artificial neural network (ANN), often just called a “neural network” (NN), is an interconnected group of artificial neurons that uses a mathematical model or computational model for information processing based on a connectionist approach to computation.

Backpropagation Algorithm: A supervised learning technique used for training artificial neural networks. It was first described by Paul Werbos in 1974, and further developed by David E. Rumelhart, Geoffrey E. Hinton and Ronald J. Williams in 1986. It is most useful for feed-forward networks (networks that have no feedback, or simply, that have no connections that loop).

Clustering: The classification of objects into different groups, or more precisely, the partitioning of a data set into subsets (clusters), so that the data in each subset (ideally) share some common trait - often proximity according to some defined distance measure. Data clustering is a common technique for statistical data analysis, which is used in many fields, including machine learning, data mining, pattern recognition, image analysis and bioinformatics.

Document Enhancement: Accentuation of certain desired features, which may facilitate later processing steps such as segmentation or object recognition.

Hierarchical Agglomerative Clustering: Hierarchical Clustering algorithms find successive clusters using previously established clusters. Agglomerative algorithms begin with each element as a separate cluster and merge them into successively larger clusters.

Multilayer Perceptron (MLP): This class of artificial neural networks consists of multiple layers of computational units, usually interconnected in a feed-forward way. Each neuron in one layer has directed connections to the neurons of the subsequent layer. In many applications the units of these networks apply a sigmoid function as an activation function.

Optical Character Recognition (OCR): A type of computer software designed to translate images of handwritten or typewritten text (usually captured by a scanner) into machine-editable text, or to translate pictures of characters into a standard encoding scheme representing them (e.g. ASCII or Unicode). OCR began as a field of research in pattern recognition, artificial intelligence and machine vision.

Supervised Learning: A machine learning technique for creating a function from training data. The training data consist of pairs of input objects (typically vectors), and desired outputs. The output of the function can be a continuous value (called regression), or can predict a class label of the input object (called classification). The task of the supervised learner is to predict the value of the function for any valid input object after having seen a number of training examples (i.e. pairs of input and target output).

Bio-Inspired Algorithms in Bioinformatics I

José Antonio Seoane Fernández

University of A Coruña, Spain

INTRODUCTION

Large worldwide projects like the Human Genome Project, which in 2003 successfully concluded the sequencing of the human genome, and the recently terminated Hapmap Project, have opened new perspectives in the study of complex multigene illnesses: they have provided us with new information to tackle the complex mechanisms and relationships between genes and environmental factors that generate complex illnesses (Lopez, 2004; Dominguez, 2006).

Thanks to these new genomic and proteomic data, it becomes increasingly possible to develop new medicines and therapies, establish early diagnoses, and even discover new solutions for old problems. These tasks however inevitably require the analysis, filtration, and comparison of a large amount of data generated in a laboratory with an enormous amount of data stored in public databases, such as the NCBI and the EBI.

Computer sciences equip biomedicine with an environment that simplifies our understanding of the biological processes that take place in each and every organizational level of live matter (molecular level, genetic level, cell, tissue, organ, individual, and population) and the intrinsic relationships between them.

Bioinformatics can be described as the application of computational methods to biological discoveries (Baldi, 1998). It is a multidisciplinary area that includes computer sciences, biology, chemistry, mathematics, and statistics. The three main tasks of bioinformatics are the following: develop algorithms and mathematical models to test the relationships between the members of large biological datasets, analyze and interpret heterogeneous data types, and implement tools that allow the storage, retrieve, and management of large amounts of biological data.

BACKGROUND

The following section describes some of the problems that are most commonly found in bioinformatics.

Interpretation of Gene Expression

The expression of genes is the process by which the codified information of a gene is transformed into the necessary proteins for the development and functioning of the cell. In the course of this process, small sequences of ARN, also called ARN messengers, are formed by transcription and subsequently *translated* into proteins.

The amount of expressed mRNA can be measured with various methods, such as gel electrophoresis, but large numbers of simultaneous expression analyses are usually carried out with microarrays (Quackenbush, 2001), which make it possible to obtain the simultaneous expression of tens of thousands of genes; such an amount of data can only be analyzed with the help of an informatic process.

Among the most common tasks in this type of analysis is the task to find the differences between, for instance, a patient and a test that determines whether a gene is expressed or not. These tasks can be divided into classical problems of classification and clustering. Clustering is used not only in experiments of microarrays (to identify groups of genes with similar expressions), but also suggests functional relationships between the members of the cluster.

Alignment of ADN, ARN, and Protein Sequences

Sequences alignment consists in superposing two or more sequences of both nucleotides (ADN and ARN) and amino acids (proteins) in order to compare them and analyze the sequence parts that are alike and unlike.

The optimal alignment is that which mainly shows correspondences between the nucleotides or amino acids and is therefore said to have the highest score. This alignment may or may not have a biological meaning. There are two types of alignment: the global alignment, which maximizes the number of coincidences in the entire sequence, and the local alignment, which looks for similar regions in large sequences that are normally highly divergent. The most commonly used technique to implement alignments is dynamic programming by means of the Smith-Waterman algorithm (Smith, 1981), which explores all the possible comparisons in the sequences.

Another problem in sequences alignment is multiple alignment (Wallace, 2005), which consists in aligning three or more sequences of ADN, ARN, or proteins, and is generally used to search for evolutive relationships between these sequences. The problem is equivalent to that of simple sequences alignment, but takes into consideration the n sequences that are to be compared. The complexity of the algorithm increases exponentially with the number of sequences to compare.

Identification of the Gene Regulatory Network

All the information of a living organism's genome is stored in each and every one of its cells. Whereas the genome is used to synthesize information on all the body cells, the regulating network is in charge of guiding the expression of a given set of genes in one cell rather than another so as to form certain types of cells (cellular differentiation) or carry out specific functions related to spatial and temporal localization; in other words, it makes the genes express themselves when and where necessary. The role of a gene regulatory network therefore consists in integrating the dynamic behaviour of the cell and the external signals with the environment of the cell, and to guide the interaction of all the cells so as to control the process of cellular differentiation (Geard, 2004). Inferring this regulating network from the cellular expression data is considered to be one of the most complex problems in bioinformatics (Akustsu, 1999).

Construction of Phylogenetic Trees

A phylogenetic tree (Setúbal, 1999) is a tree that shows the evolutionary relationships between various spe-

cies of individuals that are believed to have common descent. Whereas traditionally morphological characteristics are used to carry out such analyses, in the present case we will study molecular phylogenetic trees, which use sequences of nucleotides or amino acids for classification. The construction of these trees is initially based on algorithms for multiple sequences alignment, which allows us to classify the evolutive relationships between homologue genes present in various species. In a second phase, we must calculate the genetic distance between each pair of sequences in order to represent them correctly in the tree.

Gene Finding and Mapping

Gene finding (Fickett, 1996) basically consists in identifying genes in an ADN chain by recognizing the sequence that initiates the codification of the gene or *gene promoter*. When the protein that will interpret the gene finds the sequence of that promoter, we know that the next step is the recognition of the gene.

Gene mapping (Setúbal, 1999) consists in creating a genetic map by assigning genes to a position inside the chromosome and by indicating the relative distance between them. There are two types of mapping. Physical or *cytogenetic* mapping, on the one hand, consists in dividing the chromosome into small labelled fragments. Once divided, they must be ordered and situated in their correct position in the chromosome. Link mapping, on the other hand, shows the position of some genes with respect to others. The latter mapping type has two inconveniences: it does not provide the distance between the genes, and it is unable to provide the correct order if the genes are very close to each other.

Prediction of DNA, RNA, and Protein Structure

The DNA and RNA sequences are folded into a tridimensional structure that is determined by the order of the nucleotides within the sequence. Under the same environmental conditions, the tridimensional structure of these sequences implies a diverging behaviour. Since the secondary structure of the nucleic acids is a factor that affects the link of both DNA molecules and RNA molecules, it is essential to know these structures in order to analyze a sequence.

The prediction of the folds that determine the RNA structure is an important factor in the understanding of

many biological processes, such as translation in the RNA Messenger, replication of RNA chains in viruses, and the function of structural RNA and RNA/proteins complexes.

The tridimensional structure of proteins is extremely diverse, going from completely fibrous to nodular. Predicting the folds of proteins is important, because a protein's structure is closely related to its function. The experimental determination of the proteinic structure as such helps us to find the proteinic function and allows us to design synthetic proteins that can be used as medicines.

BIO-INSPIRED ALGORITHMS

The basic principle of bio-inspired algorithms is to use analogies with natural systems in order to solve problems. By simulating the behaviour of natural systems, these algorithms design heuristic, non-deterministic methods for searching, learning, behaviour, etc. (Forbes, 2004).

Artificial Neural Networks

Artificial neural networks (McCulloch, 1943)(Hertz, 1991)(Bishop, 1995) (Rumelhart, 1986) (ANNs) are computational models inspired on the behaviour of the nervous system. Even though their development is based on the modelling of biological processes in the brain, there are considerable differences between the processing elements of ANNs and actual neurons.

ANNs consist of unit networks that are interconnected and organized in layers that evolve in the course of time. The main features of these systems are the following: Self-Organization and Adaptability: Allow robust and adaptive processing, adaptive training, and self-organizing networks; Non-linear processing: Increase the network's capacity to approach, classify, and be immune to noise; Parallel processing: use a large number of processing units with a high level of interconnectivity.

ANNs can be classified according to their learning type: Supervised learning neural networks: the network learns relationships between the input and output data. The input data are passed on to the input layer and propagate through the network architecture until they reach the output layer. The output obtained in this output layer is compared to the expected output,

and subsequently the weights of the interconnections are modified so as to minimize the error between the obtained and the expected output; Non-supervised learning networks: In this type of learning, none of the expected output types is passed on to the network, but the network itself searches for the differences between the inputs and separates the data accordingly.

Evolutionary Computation

Evolutionary computation (Rechenberg, 1971)(Holland, 1975) is a technique that is inspired on evolutive biological strategies: genetic algorithms, for example, use biological techniques of cross-over, mutation, and selection to solve searching and optimization problems. Each of these operators has an impact on one or more chromosomes, i.e. possible solutions to the problem, and generates another series of chromosomes, i.e. the following generation of solutions. The algorithm is executed iteratively and as such takes the population through the generations until it finds an optimal solution. Another strategy of evolutionary computation is genetic programming (Koza 1990), which uses the same operators as the genetic algorithms to develop the optimal program to solve a problem.

Swarm Intelligence

Swarm intelligence (Beni, 1989)(Bonabeau, 2001)(Engelbrecht, 2005) is a recent family of bio-inspired techniques based on the social or collective behaviour of groups such as ants, bees, etc., insects which have very limited capacities as individuals, but form groups to carry out complex tasks.

Immune Artificial System

The immune artificial system (Farmer, 1986)(Dasgupta, 1999) is a new computational paradigm that has appeared in recent years and is based on the immune system of vertebrates. The biological immune system is a parallel and distributed adaptive system that uses learning, memory, and associative recuperation to solve problems of recognition and classification. It particularly learns to recognize patterns, remember them, and use their combinations to build efficient pattern detectors. From the point of view of information processing, these interesting features are used

in the artificial immune system to successfully solve complex problems.

CONCLUSION

This article describes the main problems that are presently found in the field of bio-informatics. It also presents some of the bio-inspired computation techniques that provide solutions for problems related to classification, clustering, minimization, modelling, etc. The following article will describe a series of techniques that allow researchers to solve the above problems with bio-inspired models.

KEY TERMS

Amino Acid: One of the 20 chemical building blocks that are joined by amide (peptide) linkages to form a polypeptide chain of a protein.

Artificial Immune System: Biologically inspired computer algorithms that can be applied to various domains, including fault detection, function optimization, and intrusion detection. Also called *computer immune system*.

Electrophoresis: The use of an external electric field to separate large biomolecules on the basis of their charge by running them through acrylamide or agarose gel.

Messenger RNA: The complementary copy of DNA formed from a single-stranded DNA template during the transcription that migrates from the nucleus to the cytoplasm where it is processed into a sequence carrying the information to code for a polypeptide domain.

Microarray: A 2D array, typically on a glass, filter, or silicon wafer, upon which genes or gene fragments are deposited or synthesized in a predetermined spatial order allowing them to be made available as probes in a high-throughput, parallel manner.

Nucleotid: A nucleic acid unit composed of a five carbon sugar joined to a phosphate group and a nitrogen base.

Swarm Intelligence: An artificial intelligence technique based on the study of collective behaviour in decentralised, self-organised systems.

Transcription: The assembly of complementary single-stranded RNA on a DNA template.

Translation: The process of converting RNA to protein by the assembly of a polypeptide chain from an mRNA molecule at the ribosome.

Bio-Inspired Algorithms in Bioinformatics II

University of A Coruña, Spain

Mónica Miguélez Rico

University of A Coruña, Spain

INTRODUCTION

Our previous article presented several computational models inspired on biological models, such as neural networks, evolutionary computation, swarm intelligence, and the artificial immune system. It also explained the most common problems in bioinformatics to which these models can be applied.

The present article presents a series of approaches to bioinformatics tasks that were developed by means of artificial intelligence techniques and focus on bio-inspired algorithms such as artificial neural networks and evolutionary computation.

BACKGROUND

Previous publications have focused on the use of bio-inspired and other artificial intelligence techniques. Keedwell (2005) has summarized the foundations of molecular biology, the main problems in bioinformatics, and the existing solutions based on artificial intelligence. Baldi (Baldi, 2001) also describes various techniques for problem-solving in bioinformatics. Other generalizing works on this subject can be found in (Larrañaga, 2006), whereas more specialized works focus on solutions based on evolutionary computation (Pal, 2006) or artificial life (Das, 2007).

Bio-Inspired Techniques

The following section describes how the techniques that were mentioned in our article *Bio-inspired Algorithms in Bioinformatics I* have been used to solve the main problems in bioinformatics.

Gene Expression

We start by describing how artificial intelligence techniques have contributed to the interpretation of

genes expression. Artificial neural networks (ANNs) have been applied extensively to the classification of genetic data. One of the most commonly used architectures for the classification of this type of data is the multilayer perceptron. Many works use this architecture for diagnosis (Wang, 2006) (Wei, 2005) (Narayanan, 2004) and obtain very good results; most of these approaches use artificial neural networks to discover and classify interactions between variables (genes expression values).

Statnikov (2005) and Lee (2005) compare several classification techniques, such as ANNs using back-propagation, probabilistic ANNs, Support Vector Machines (SVM), K-Nearest Neighbour (KNN), and other statistical methods for the classification of data that issue from microarrays expression tests. In this type of genetic expression data classification, we can also find a combination of ANNs and genetic programming: Ritchie (Ritchie, 2004) codifies into each individual of the genetic algorithm (GA) the architecture and weights of the network, so that the genetic programming optimizes the network to minimize the error between the output layer and the expected output, or the hybrids between the ANNs and the genetic algorithms of Kim (Kim, 2004) and Keedwell (Keedwell, 2005).

Genetic programming (GP) as such has also been used (Gilbert, 2000; Hong, 2004; Langdon, 2004; Hong, 2006) to classify the results of an expression analysis. The advantage of GP is that it classifies the genes while selecting the relevant ones (Muni, 2006). The training set of the expression data *patients* and *control* are the input for the GP algorithm, which evaluates whether or not the example is a control. The result is one or a set of classification rules. The advantage of using GP instead of other techniques such as SVM is that it is transparent: the mechanism used to classify the examples of the patients can be evaluated (Driscoll, 2003).

Whereas the above studies all classify by means of supervised learning, the following section presents various expression analysis methods for clustering that

use non-supervised learning. This type of analysis is very useful to discover gene groups that are potentially related or associated to the illness. A comparison between the most commonly applied methods, using both real and simulated data, can be found in the works of Thalamuthu (2006), Handl (2005), and Sheng (2005). Even though these methods have provided good results in certain cases (Spellman, 1998; Tamayo, 1999; Mavroudi, 2002), some of their inherent problems, such as the identification of the number of clusters, the clustering of the “outliers”, and the complexity associated to the large amount of data that are being analysed, often complicate their use for expression analysis (Sherlock, 2001). These deficiencies were tackled in a series of second generation clustering algorithms, among which the self-organising trees (Herrero, 2001; Hsu, 2003).

Another interesting approach for expression analysis is the use of the artificial immune system, which can be observed in the works of Ando (Ando 2003), who applies immune recognition to classification by making the system select the most significant genes and optimize their weights in order to obtain classification rules. Finally, de Sousa, de Castro, and Bezerra apply this technique to clustering (de Sousa, 2004)(de Castro, 2001)(Bezerra, 2003).

Sequence Alignment

Solutions based on genetic algorithms, such as the SAGA (Notredame, 1996), the RAGA, the PRAGA (Notredame, 1997, 2002), and others (O’Sullivan, 2004; Nguyen, 2002; Yokohama, 2001), have been applied to sequence alignment since the very beginning. The most common method consists in codifying the alignments as individuals inside the genetic algorithm. There are also hybrid solutions that use not only GA but also dynamic programming (Zhang, 1997, 1998); and finally, there is the application of artificial life algorithms, in particular the *ant colony* algorithm (Chen, 2006; Moss, 2003).

Genetic Networks

In order to correct the problem of the inference of genetic networks, the structure of the regulating network and the interactions between the participating genes must be predicted. The expression of the genes is regulated by transitions of states in which the levels of expression of the involved genes are updated simultaneously.

ANNs have been used to model these networks. Examples of such approaches can be found in the works of Krishna, Keedwell, and Narayanan (Keedwell, 2003)(Krishna, 2005).

Genetic algorithms (Ando, 2001)(Tominaga, 2001) and hybrid RNA-genetic approaches (Keedwell, 2005) have also been used for the same purpose.

Phylogenetic Trees

Normally, exhaustive search techniques for the creation of phylogenetic trees are computationally unfeasible for more than 10 comparisons, because the number of possible solutions increases exponentially with the number of objects in the comparisons. In order to optimize these searches, researchers have used heuristics based on genetic algorithms (Skourikhine, 2000)(Kato, 2001)(Lemmon, 2002) that allow the reconstruction of the optimal trees with less computational load. Other techniques, such as the ant colony algorithm, have also been used to reconstruct phylogenetic trees (Ando, 2002)(Kummorkaew, 2004) (Perretto, 2005).

Gene Finding and Mapping

Gene mapping has been approached by methods that use only genetic algorithm (Fickett, 1996)(Murao, 2002) as well as by hybrid methods that combine genetic algorithms and statistical techniques (Gaspin, 1997).

The problem of gene searching and in particular promoter searching has been approached by means of neural networks (Liu, 2006), neural networks optimized with genetic algorithms (Knudsen, 1999), conventional genetic algorithms (Kel, 1998)(Levitsky, 2003), and fuzzy genetic algorithms (Jacob, 2005).

Structure Prediction

The tridimensional structure of DNA was predicted with genetic algorithms (Beckers, 1997) by codifying the torsional angles between the atoms of the DNA molecule as solutions of the genetic algorithm. Another approach was the development of hybrid strategies of ANNs and GAs (Parbhane, 2000), in which the network approaches the non-linear relations between the inputs and outputs of the data set, and the genetic algorithm searches within the network inputs space to optimize the output. In order to predict the secondary structure of the RNA, the system calculates the minimum free

energy of the structure for all the different combinations of the hydrogen links. There are approaches that use genetic algorithms (Shapiro, 2001)(Wiese, 2003) and artificial neural networks (Steeg, 1997).

Artificial neural networks have been applied to the prediction of protein structures (Qian, 1988)(Sasagawa, 1992), and so have genetic algorithms. A compilation of the application of evolutionary computation in protein structures prediction can be found in (Schulze-Kremer, 2000). Swarm intelligence, and optimization by ant colony in particular, have been applied to structures prediction (Shmygelska, 2005)(Chu, 2005) and artificial immune system (Nicosia, 2004)(Cutello, 2007).

CONCLUSION

This article presents a compendium of the most recent references on the application of bio-inspired solutions such as evolutionary computation, artificial neural networks, swarm intelligence, and artificial immune system to the most common problems in bioinformatics.

KEY TERMS

Bioinformatics: The use of applied mathematics, informatics, statistics, and computer science to study biological systems.

Gene Expression: The conversion of information from gene to protein via transcription and translation.

Gene Mapping: Any method used for determining the location of a relative distance between genes on a chromosome.

Gene Regulatory Network: Genes that regulate or circumscribe the activity of other genes; specifically, genes with a code for proteins (repressors or activators) that regulate the genetic transcription of the structural genes and/or regulatory genes.

Phylogeny: The evolutionary relationships among organisms. The patterns of lineage branching produced by the true evolutionary history of the organism that is being considered.

Sequence Alignment: The result of comparing two or more gene or protein sequences in order to determine

their degree of base or amino acid similarity. Sequence alignments are used to determine the similarity, homology, function, or other degrees of relatedness between two or more genes or gene products.

Structure Prediction: Algorithms that predict the 2d or 3D structure of proteins or DNA molecules from their sequences.

Bioinspired Associative Memories

Roberto A. Vazquez

Center for Computing Research, IPN, Mexico

Humberto Sossa

Center for Computing Research, IPN, Mexico

INTRODUCTION

An **associative memory** AM is a special kind of neural network that allows recalling one output pattern given an input pattern as a key that might be altered by some kind of noise (additive, subtractive or mixed). Most of these models have several constraints that limit their applicability in complex problems such as **face recognition** (FR) and **3D object recognition** (3DOR).

Despite of the power of these approaches, they cannot reach their full power without applying new mechanisms based on current and future study of biological neural networks. In this direction, we would like to present a brief summary concerning a new associative model based on some neurobiological aspects of human brain. In addition, we would like to describe how this **dynamic associative memory** (DAM), combined with some aspects of **infant vision system**, could be applied to solve some of the most important problems of pattern recognition: FR and 3DOR.

BACKGROUND

Humans possess several capabilities such as learning, recognition and memorization. In the last 60 years, scientists of different communities have been trying to implement these capabilities into a computer. Along these years, several approaches have emerged, one common example are neural networks (McCulloch & Pitts, 1943) (Hebb, 1949) (Rosenblatt, 1958). Since the rebirth of neural networks, several models inspired in the neurobiological process have emerged. Among these models, perhaps the most popular is the feed-forward multilayer perceptron trained with the back-propagation algorithm (Rumelhart & McClelland, 1986). Other neural models are associative memories, for example (Anderson, 1972) (Hopfield, 1982) (Sussner, 2003) (Sossa, Barron & Vazquez, 2004). On the other hand,

the brain is not a huge fixed neural network as had been previously thought, but a dynamic, changing neural network. In this direction, several models have emerged for example (Grossberg, 1967) (Hopfield, 1982).

In most of these classical neural networks approaches, synapses are only adjusted during the training phase. After this phase, synapses are no longer adjusted. Modern brain theory uses continuous-time model based on current study of biological neural networks (Hecht-Nielsen, 2003). In this direction, the next section described a new dynamic model based on some aspects of biological neural networks.

Dynamic Associative Memories (DAMs)

The dynamic associative model is not an iterative model as Hopfield's model. It emerges as an improvement of the model and results presented in (Sossa, Barron & Vazquez, 2007).

Let $\mathbf{x} \in \mathbf{R}^n$ and $\mathbf{y} \in \mathbf{R}^m$ an input and output pattern, respectively. An association between input pattern \mathbf{x} and output pattern \mathbf{y} is denoted as $(\mathbf{x}^k, \mathbf{y}^k)$, where k is the corresponding association. Associative memory: \mathbf{W} is represented by a matrix whose components w_{ij} can be seen as the synapses of the neural network.

If $\mathbf{x}^k = \mathbf{y}^k \forall k = 1, \dots, p$ then \mathbf{W} is auto-associative, otherwise it is hetero-associative. A distorted version of a pattern \mathbf{x} to be recalled will be denoted as $\tilde{\mathbf{x}}$. If an associative memory \mathbf{W} is fed with a distorted version of \mathbf{x}^k and the output obtained is exactly \mathbf{y}^k , we say that recalling is robust.

Because of several regions of the brain interact together in the process of learning and recognition (Laughlin & Sejnowski, 2003), in the dynamic model there are defined several interacting areas; also it integrated the capability to adjust synapses in response to an input stimulus. Before the brain processes an input pattern, it is hypothesized that pattern is transformed and codified by the brain. This process is simulated

using the procedure introduced in (Sossa, Barron & Vazquez, 2004).

This procedure allows computing *coded patterns* and *de-coding patterns* from input and output patterns allocated in different interacting areas of the model. In addition a simplified version of \mathbf{x}^k denoted by s_k is obtained as:

$$s_k = s(\mathbf{x}^k) = \mathbf{mid} \mathbf{x}^k \quad (1)$$

where **mid** operator is defined as $\mathbf{mid} \mathbf{x} = x_{(n+1)/2}$.

When the brain is stimulated by an input pattern, some regions of the brain (interacting areas) are stimulated and synapses belonging to these regions are modified. In this model, the most excited interacting area is called *active region* (AR) and could be estimated as follows:

$$ar = r(\mathbf{x}) = \arg \left(\min_{i=1}^p |s(\mathbf{x}) - s_i| \right) \quad (2)$$

Once computed the *coded patterns*, the *de-coding patterns* and s_k we can build the associative memory.

Let $\{(\bar{\mathbf{x}}^k, \bar{\mathbf{y}}^k) | k=1, \dots, p\}$, $\bar{\mathbf{x}}^k \in \mathbf{R}^n$, $\bar{\mathbf{y}}^k \in \mathbf{R}^m$ a fundamental set of associations (coded patterns). Synapses of associative memory \mathbf{W} are defined as:

$$w_{ij} = \bar{y}_i - \bar{x}_j \quad (3)$$

In short, building of the associative memory can be performed in three stages as:

1. Transform the fundamental set of association into coded and de-coding patterns.
2. Compute simplified versions of input patterns by using equation 1.
3. Build \mathbf{W} in terms of coded patterns by using equation 3.

There are synapses that can be drastically modified and they do not alter the behavior of the associative memory. On the contrary, there are synapses that can only be slightly modified to do not alter the behavior of the associative memory; we call this set of synapses *the kernel* of the associative memory and it is denoted by \mathbf{K}_w .

Let $\mathbf{K}_w \in \mathbf{R}^n$ the kernel of an associative memory \mathbf{W} . A component of vector \mathbf{K}_w is defined as:

$$kw_i = \mathbf{mid}(w_{ij}), j=1, \dots, m \quad (4)$$

Synapses that belong to \mathbf{K}_w are modified as a response to an input stimulus. Input patterns stimulate some ARs, interact with these regions and then, according to those interactions, the corresponding synapses are modified. An adjusting factor denoted by Δw can be computed as:

$$\Delta w = \Delta(\mathbf{x}) = s(\bar{\mathbf{x}}^{ar}) - s(\mathbf{x}) \quad (5)$$

where ar is the index of the AR.

Finally, synapses belonging to \mathbf{K}_w are modified as:

$$\mathbf{K}_w = \mathbf{K}_w \oplus (\Delta w - \Delta w_{old}) \quad (6)$$

where operator \oplus is defined as $\mathbf{x} \oplus e = x_i + e \quad \forall i=1, \dots, m$.

Once synapses of the associative memory have been modified in response to an input pattern, every component of vector $\bar{\mathbf{y}}$ can be recalled by using its corresponding input vector $\bar{\mathbf{x}}$ as:

$$\bar{y}_i = \mathbf{mid}(w_{ij} + \bar{x}_j), j=1, \dots, n \quad (7)$$

In short, pattern $\bar{\mathbf{y}}$ can be recalled by using its corresponding key vector $\bar{\mathbf{x}}$ or $\tilde{\mathbf{x}}$ in six stages:

1. Obtain index of the active region ar by using equation 2.
2. Transform \mathbf{x}^k using de-coding pattern $\hat{\mathbf{x}}^{ar}$ by applying the following transformation: $\tilde{\mathbf{x}}^k = \mathbf{x}^k + \hat{\mathbf{x}}^{ar}$.
3. Compute adjust factor $\Delta w = \Delta(\tilde{\mathbf{x}})$ by using equation 5.
4. Modify synapses of associative memory \mathbf{W} that belong to \mathbf{K}_w by using equation 6.
5. Recall pattern $\hat{\mathbf{y}}^k$ by using equation 7.
6. Obtain \mathbf{y}^k by transforming $\hat{\mathbf{y}}^k$ using de-coding pattern $\hat{\mathbf{y}}^{ar}$ by applying transformation: $\mathbf{y}^k = \hat{\mathbf{y}}^k - \hat{\mathbf{y}}^{ar}$.

The formal set of propositions that support the correct functioning of this dynamic model, the main advantages against other classical models and some interesting applications of this model are described in (Vazquez, Sossa & Garro, 2006) and (Vazquez & Sossa, 2007).

In general, we distinguish two main parts in this model: a part concerning to the determination of the AR (PAR) and a part concerning to pattern recall (PPR). PAR (first step during recall procedure) sends a signal to PPR (remaining steps for recall procedure) and indicates the region activated by the input pattern.

FACE AND 3D OBJECT RECOGNITION USING SOME ASPECTS OF THE INFANT VISION SYSTEM AND DAMS

Several statistical computationally expensive techniques (dimension reduction techniques) such as principal component analysis and factor analysis have been proposed, for solving the FR and 3DOR problem.

Instead of using the complete version of the describing pattern X of any face or object, a simplified version from describing pattern X could be used to recognize a face or an object. In many papers, authors have used PCA to perform FR and other tasks, refer for example to (Turk & Pentland, 1991).

During early developmental stages, there are communication pathways between the visual and other sensory areas of the cortex, showing how the biological network is self-organizing. Within a few months of birth, the baby is able to differentiate one face or objects (toys) from others. Barlow hypothesized that for a neural system one possible way of capturing the statistical structure was to remove the redundancy in the sensory outputs (Barlow, 2001).

By taking into account the theory of Barlow, we propose a novel method for FR and 3DOR based on some biological aspects of infant vision. The biological hypotheses of this proposal are based on the role of the response to **low frequencies** at early stages, and some conjectures concerning how an infant detects subtle features (**stimulating points** (SP)) in a face or object (Mondloch et al., 1999; Acerra, Burnod, & Schonen, 2002).

The proposal consists on several DAMs used to recognize different images of faces and objects. As the infant vision responds to low frequencies of the signal,

a low-pass filter is first used to remove high frequency components from the image. After that, we divide the image in different parts (sub-patterns). Then, over each sub-pattern, we detect subtle features by means of a random selection of SPs. Preprocessing images used to remove high frequencies and random selection of SPs contribute to eliminating redundant information and help the DAMs to learn efficiently the faces or the objects. At last, each DAM is fed with these sub-patterns for training and recognition.

Response to Low Frequencies

Instead of using a filter that exactly simulates the infant vision system behavior at any stage, we use a low-pass filter to remove high frequency. This kind of filter could be seen as a slight approximation of the infant vision system due to it eliminates high frequency components from the pattern, see Figure 1.

Random Selection

In the DAM model, the simplified version of an input pattern is the middle value of input pattern. In order to simulate the random selection of the infant vision system we have substituted **mid** operator with **rand** operator defined as follows:

$$\mathbf{rand} \mathbf{x} = x_{sp} \quad (8)$$

where $sp = \text{random}(n)$ is a random number between zero and the length of input pattern. sp is a constant value computed at the beginning of the building phase and represents a SP. During recalling phase sp takes the same value.

rand operator uses a uniform random generator to select a component over each part of the pattern. We adopt this operator based on the hypothetical idea about infants are interested into sets of features where each set is different with some intersection among them. By selecting features at random, we conjecture that at least we select a feature belonging to these sets.

Implementation of the Proposal

During recalling, each DAM recovers a part of the image based on the AR of each DAM. However, a part of the image could be wrongly recalled because its

Figure 1. Images filtered with masks of different size. Each group could be associated with different stages of infant vision system.

corresponding AR could be wrongly determined due to some patterns do not satisfy the prepositions that guarantee perfect recall. To avoid this, we use an integrator. Each DAM determines an AR, the index of the AR is sent to the integrator, the integrator determines which was the most voted region and sends to the DAMs the index of the most voted region (the new AR).

Let $[\mathbf{I}_x^k]_{a \times b}$ and $[\mathbf{I}_y^k]_{c \times d}$ an association of images and r be the number of DAMs. Building of the nDAMs is done as follows:

1. Select filter size and apply it to the images.
2. Transform the images into a vector $(\mathbf{x}^k, \mathbf{y}^k)$ by means of the standard image scan method where vectors are of size $a \times b$ and $c \times d$ respectively.
3. Decompose \mathbf{x}^k and \mathbf{y}^k in r sub-patterns of the same size.
4. Take each sub-pattern (from the first one to the last one (r)), then take at random a SP $sp_i, i = 1, \dots, r$ and extract the value at that position.
5. Train r DAMs as in building procedure taking each sub-pattern (from the first one to the last one (r)) using **rand** operator.

Pattern \mathbf{I}_y^k can be recalled by using its corresponding key image \mathbf{I}_x^k or $\tilde{\mathbf{I}}_x^k$ as follows:

1. Select filter size and apply to the images.
2. Transform the images into a vector by means of the standard image scan method and decompose \mathbf{x}^k in r sub-patterns of the same size.
3. Use the SP, $sp_i, i = 1, \dots, r$ computed during the building phase and extract the value of each sub-pattern.
4. Determine the most voted active region using the integrator.
5. Substitute **mid** with **rand** operator in recalling procedure and apply steps from two to six as described in recalling procedure on each DAM.
6. Finally, put together recalled sub-patterns to form the output pattern.

A schematic representation of the building and recalling phases is shown in Figure 2.

Some Experimental Results

To test the accuracy of the proposal, we performed two experiments. In experiment 1, we used a benchmark (Spacek, 1996) of faces of 15 different people. In experiment 2, we use a benchmark (Nene, 1996) of 100 objects. During the training process in both experiments, the DAM performed with 100% accuracy using only one image of each person and object. During testing, the DAM performed in average with 99% accuracy for the remaining 285 images of faces (experiment 1) and 95% accuracy for the remaining 1900 images of

Figure 2. (a) Schematic representation of building phase. (b) Schematic representation of the recalling phase.

objects (experiment 2) by using different sized-filter and SPs.

Through several experiments we have tested the accuracy and stability of the proposal using different number of stimulation points, see Figure 3 and Figure 4. Because of SPs (pixels) were randomly selected, we decided to test the stability of proposal with the same configuration 20 times.

An extra experiment was performed with images partially occluded. In average, the accuracy of the proposal diminished to 80%.

While PCA dimension reduction techniques require the covariance matrix to build an Eigenspace, then to project patterns using this space to eliminate redundant information, our proposal only requires removing high frequencies by using a filter and a random selection of stimulating points.

This approach contributes to eliminating redundant information; it is less computationally expensive than PCA, and helps the DAMs or other classification tools to learn efficiently the faces or objects.

FUTURE TRENDS

Preprocessing images used to remove high frequencies and random selection of SPs contribute eliminating unnecessary information and help the DAM to learn efficiently faces and objects. Now we need to study new mechanisms based on evolutionary techniques in order to select the most important SPs. In addition, we need to test different types of filters that really simulate the behavior of the infant vision system.

In a near future, we pretend to use this proposal as a biological model to explain the learning process in infant's brain for FR and 3DOR. One step in this direction can be found in (Vazquez & Sossa, 2007).

CONCLUSION

In this paper, we have proposed a novel method for FR and 3DOR based on some biological aspects of infant vision. We have shown that by applying some aspects of the infant vision system it is possible to enhance the performance of an associative memory (or other

Figure 3. Accuracy of the proposal using different filter size. The reader can verify the accuracy of the proposal diminish after apply a filter of size greater than 25.

Figure 4. Average accuracy of the proposal. Maximum, average and minimum accuracy are sketched.

distance classifiers) and make possible its application to complex problems such as FR and 3DOR.

In order to recognize different images of face or objects we have used several DAMs. As the infant vision responds to low frequencies of the signal, a low-filter is first used to remove high frequency components from the image. Then we detected subtle features in the image by means of a random selection of SPs. At last, each DAM was fed with this information for training and recognition.

Through several experiments, we have shown the accuracy and the stability of the proposal even under occlusions. In average, the accuracy of the proposal oscillates between 95% and 99%.

The results obtained with the proposal were comparable with those obtained by means of a PCA-based method (99%). Although PCA is a powerful technique it consumes a lot of time to reduce the dimensionality of the data. Our proposal, because of its simplicity in operations, is not a computationally

expensive technique and the results obtained are comparable to those provided by PCA.

KEY TERMS

Associative Memory: Mathematical device specially designed to recall output patterns from input patterns that might be altered by noise.

Dynamic Associative Memory: A special type of associative memory composed by dynamical synapses. This memory adjusts the values of their synapses during recalling phase in response to input stimuli.

Dynamical Synapses: Synapses that modified their values in response to an input stimulus also during recalling phases.

Low-Pass Filter: Filter which removes high frequencies from an image or signal. This type of filters is used to simulate the infant vision system at early stages. Examples of these filters are the average filter or the median filter.

PCA: Principal component analysis is a technique used to reduce multidimensional data sets to lower dimensions for analysis. PCA involves the computation of the eigenvalue decomposition of a data set, usually after mean centering the data for each attribute.

Random Selection: Selection of one or more components of a vector at randomly manner. Random selection techniques are used to reduce multidimensional data sets to lower dimensions for analysis.

Stimulating Points: Characteristic points of an object in an image used during learning and recognition, which capture the attention of a child. These stimulating points are used to train the dynamic associative memory.

INTRODUCTION

The knowledge about higher brain centres in insects and how they affect the insect's behaviour has increased significantly in recent years by theoretical and experimental investigations. Nowadays, a large body of evidence suggests that higher brain centres of insects are important for learning, short-term, long-term memory and play an important role for context generalisation (Bazhenof *et al.*, 2001). Related to these subjects, one of the most interesting goals to achieve would be to understand the relationship between sequential memory encoding processes and the higher brain centres in insects in order to develop a general "insect-brain" control architecture to be implemented on simple robots. In this contribution, it is showed a review of the most important and recent results related to spatio-temporal coding and it is suggested the possibility to use continuous recurrent neural networks (CRNNs) (that can be used to model non-linear systems, in particular Lotka-Volterra systems) in order to find out a way to model simple cognitive systems from an abstract viewpoint. After showing the typical and interesting behaviors that emerge in appropriate Lotka-Volterra systems (in particular, *winnerless competition processes*) next sections deal with a brief discussion about the intelligent systems inspired in studies coming from the biology.

BACKGROUND

What do we name "computation"? Let us say a system shows the capability to compute if it has memory (or some form of internal plasticity) and it is able to

determine the appropriate decision (or behavior, or action) given a criteria and making calculations using what it senses from the outside world. Some biological systems, like several insects, have brains that show a type of computation that may be described functionally by a specific type of non-linear dynamical systems called Lotka-Volterra systems (Rabinovich *et al.*, 2000). According to our objectives, one of the first interests focuses on how an artificial recurrent neural network could model a non-linear system, in particular, a Lotka-Volterra system (Afraimovich *et al.*, 2004) and what are the typical processes that emerge in Lotka-Volterra systems (Rabinovich *et al.*, 2000). If it could be understood, then it would be clearer how the relationships between sequential memory encoding processes and the higher brain centres in insects are.

About higher brain centers (and how they affect an insect's behaviour) it is possible to stop the functioning of particular neurons under investigation during phases of experiments and gradually reestablish the functioning of the neural circuit (Gerber *et al.*, 2004). At the present, it is known that higher brain centers in insects are related on autonomous navigation, multi-modal sensory integration, and to an insect's behavioral complexity generally; evidence also suggests an important role for context generalization, short-term and long-term memory (McGuire *et al.*, 2001). For a long time, insects have inspired robotic research in a qualitative way but insect nervous systems have been under-exploited as a source for potential robot control architectures. In particular it often seems to be assumed that insects only perform 'reactive' behavior, and more complex control will need to be modeled on 'higher' animals.

SPATIO-TEMPORAL NEURAL CODING GENERATOR

The ability to process sequential information has long been seen as one of the most important functions of “intelligent” systems (Huerta *et al.*, 2004). As it will be shown afterwards, winnerless competition principle appears as a major type of mechanism of sequential memory processing. The underlying concept is that sequential memory can be encoded in a (multidimensional) dynamical system by means of heteroclinic trajectories connecting several saddle points. Each of the saddle points is assumed to be remembered for further action (Afraimovich *et al.*, 2004).

Computation over Neural Networks

Digital computers are considered universal in the sense of capability to implement any symbolic algorithm. If artificial neural networks, that have a great influence on the field of computation, are considered as a paradigm of computation, one may ask how the relation between neural networks and the classical computing paradigm is. For this question it is needed to consider, on the one hand, discrete computation (digital) and on the other hand, nondiscrete computation (analog). In terms of the first, the traditional paradigm is the Turing Machine with the Von Neumann architecture. A decade ago it was shown that artificial neural networks of analog neurons and rational weights are computationally equivalent to Turing machines. In terms of analog computation, it was also showed that three-layer feedforward nets can approximate any smooth function with arbitrary precision (Hornik *et al.*, 1990). This result was extended to show how continuous recurrent neural nets (CRNN) can approximate an arbitrary dynamical system as given by a system of n coupled first-order differential equations (Tsung, 1994; Chow and Li, 2000).

Neural Network Computation from a Dynamical-System Viewpoint

Modern dynamical systems theory is concerned with the qualitative understanding of asymptotic behaviors of systems that evolve in time. With complex non-linear systems, defined by coupled differential, difference or functional equations, it is often impossible to obtain closed-form (or asymptotically closed form) solutions. Even if such solutions are obtained,

their functional forms are usually too complicated to give an understanding of the overall behavior of the system. In such situations qualitative analysis of the limit sets (fixed points, cycles or chaos) of the system can often offer better insights. Qualitative means that this type of analysis is not concerned with the quantitative changes but rather what the limiting behavior will be (Tsung, 1994).

Spatio-Temporal Neural Coding and Winnerless Competition Networks

It is important to understand how the information is processed by computation from a dynamical viewpoint (in terms of steady states, limit cycles and strange attractors) because it gives us the possibility of manage sequential processes (Freeman, 1990). In this section it is showed a new direction in information dynamics namely the Winnerless Competition (WLC) behavior. The main point of this principle is the transformation of the incoming spatial inputs into identity-temporal output based on the intrinsic switching dynamics of a dynamical system. In the presence of stimuli the sequence of the switching, whose geometrical image in the phase space is a heteroclinic contour, uniquely depends on the incoming information.

Consider the generalized Lotka-Volterra system ($N=3$):

$$\begin{aligned}\dot{a}_1 &= a_1 [1 - (a_1 + \rho_{12}a_2 + \rho_{13}a_3)] \\ \dot{a}_2 &= a_2 [1 - (a_2 + \rho_{21}a_1 + \rho_{23}a_3)] \\ \dot{a}_3 &= a_3 [1 - (a_3 + \rho_{31}a_1 + \rho_{32}a_2)]\end{aligned}$$

If the following matrix and parameter conditions are satisfied,

$$(\rho_{ij}) = \begin{pmatrix} 1 & \alpha_1 & \beta_1 \\ \beta_2 & 1 & \alpha_2 \\ \alpha_3 & \beta_3 & 1 \end{pmatrix}$$

$$0 < \alpha_i < 1 < \beta_i$$

When the coefficients fulfill that $\alpha_1 = \alpha_2 = \alpha_3 < 1$ and $\beta_1 = \beta_2 = \beta_3 > 1$, we have three cases:

1. Stable equilibrium with all three components simultaneously present/working.
2. Three equilibria (1,0,0), (0,1,0) and (0,0,1) all stable, each one attainable depending on initial conditions.

Figure. 1. Topology of the behavior in the phase space of WLC neurons net in a 3D. The axes represent the addresses of the oscillatory connections between the processing units ($\alpha = 0.5$, $\beta = 1.8$, $x(0) = 1.01$, $y(0) = 1.01$, $z(0) = 0.01$).

3. Neither equilibrium points nor periodic solutions are asymptotically stable and we have wandering trajectories defining Winnerless Competition (WLC) behaviour

The advantages of dealing with Lotka-Volterra systems are important. It has been shown above how a Winnerless competition process can emerge in a generalized Lotka-Volterra system. Also it is known that this type of process is generalizable to any dynamical system and that any dynamical system can be represented by using recurrent neural networks (Hornik *et al.*, 1990). From this point of view, winnerless competition processes can be obtained whenever that exists a boundary condition: the Lotka-Volterra system must be of any dimension n greater than three to find Winnerless competition behavior. In the following, it is assumed that Lotka-Volterra systems approximate arbitrarily closely the dynamics of any finite-dimensional dynamical system for any finite time and we will assume and concentrate in showing them as a type of neural nets with great interest for applications (Hopfield, 2001). Various attempts at modeling the complex dynamics in insect brains have been made (Nowotny *et al.*, 2004; Rabinovich *et al.* 2001), and it is suggested that simple CRNN systems (Continuous and recurrent neural network) could be an alternative framework to implement competing processes between neurons that generate spatio-temporal patterns to codify memory in a similar way simplest living systems do (Rabinovich *et al.* 2006). Recurrent neural networks of competing neuron (inspired in how higher brain centres in insects

work) would allow to explore how building sequential memory and might suggest control architectures of insect-inspired robotic systems.

Winnerless Competition Systems Generate Adaptive Behavior

Some features of the winnerless competition systems seem to be very promising to use these systems to model the activity and the design of intelligent artefacts. It is focused on some of the results of previous theoretical studies of some authors on systems of n elements coordinated with excitement-inhibition relations (Rabinovich *et al.*, 2001). These systems show:

- **Large Capacity:** A heteroclinic (spatiotemporal) representation provides greatly increased capacity to the system. Because sequences of activity are combinatorial across elements and time, overlap between representations can be reduced, and the distance in phase space between orbits can be increased.
- **Sensitivity (to similar stimulus) and, simultaneously, capacity for categorization:** This is because the heteroclinic linking of a specific set of saddle points is always unique. Two like stimuli, activating greatly overlapping subsets of a network, may become easily separated because small initial differences will become amplified in time.
- **Robustness:** In the following sense, the attractor of a perturbed system remains in a small neighbor-

hood of the “unperturbed” attractor (robustness as topological similarity of the perturbed pattern).

All these important features emerge from the dynamic of the Lotka-Volterra system. There are more examples: in [Nepomnyashchikh *et al.*, 2003] is described a simple chaotic system of coupled oscillators that shows a complex and fruitful adaptive behaviour; the interaction among the activity of elements in the model and external inputs give rise to an emergence of searching rules from basic properties of nonlinear systems (rules which have not been pre-programmed explicitly) and with obvious adaptive value. More in detail: the adaptive rules are autonomous (the system selects an appropriate rule with no instructions from outside), and they are the result of interaction between intrinsic dynamics of the system and dynamics of the environment. These rules emerge, in a spontaneous way, because of the non-linearity in the simple system.

Winnerless Competition for Computing and Interests in Robotics

The suggestion of using heteroclinic trajectories with computing purposes shows advantages for robotics interests. It is known that very simple dynamical systems are equivalent to Turing machines and also that computing with heteroclinic orbits adds to the classical computing the feature of high sensitivity to initial conditions increasing. If we consider artefacts with computation processes ordered by winnerless competition behaviour, the artefacts will have great ability to process, manage and store sequential information. In spite of the history of studies of sequential learning and memory, little is known about dynamical principles of storing and remembering of multiple events and their temporal order by neural networks. This principle called winnerless competition can be a very useful mechanism to explore and model sequential and scheduled processes in industrial and robotic problems.

FUTURE TRENDS

Computation by heteroclinic orbits provides new perspectives to traditional computing. Because of its features, it could be interesting building such a kind of bio-inspired systems based in Winnerless competition processes. Evolution has chosen the nonlinear dynamical

phenomena as the basis of the adaptive behaviour patterns of the living organisms and these systems show, in one hand, the coexistence of sensitivity (ability to distinguish distinct, albeit similar, inputs) and robustness (ability to classify similar signals receptions as the same one). If we are able to reproduce the same characteristics in artificial intelligent architectures, will make it easier to go beyond the actual limitations into the intelligent systems applied to the real problems.

CONCLUSION

It has been summarized how a system architecture whose stimulus-dependent dynamics reproduces spatio-temporal features could be able to code and build a memory inspired in the higher brain centres of insects (Nowotny *et al.*, 2004). Beyond the biological observations which suggested these investigations, recurrent neural networks where winnerless competition processes can emerge, provide an attractive model for computation because of their large capacity as well as their robustness to noise contamination. It has been showed an interesting tool (using control and synchronization of spatio-temporal patterns) to transfer and process information between different neural assemblies for classification problems in, eventually, several industrial environments. For example, winnerless competition processes could be able to solve the fundamental contradiction between sensitivity and generalizing of the recognition, multistability and robustness to the noise in real processes (Rabinovich *et al.*, 2000). For classification tasks, is useful to get models that could be reproducible. In the language of non-linearity, this is possible only if the system is strongly dissipative (in other words, if it can rapidly forget its initial state). On the other hand, a useful classifier system should be sensitive to small variations in the inputs, so that fine discriminations between similar but not identical stimuli are possible. Winnerless competition principle shows both features.

KEY TERMS

Adaptive Behaviour: Type of behavior that allows an individual to substitute a disruptive behavior to something more constructive and able to adapt to a given situation.

Bio-Inspired Techniques: Bio-inspired systems and tools are able to bring together results from different areas of knowledge, including biology, engineering and other physical sciences, interested in studying and using models and techniques inspired from or applied to biological systems.

Computational System: Computation is a general term for any type of information processing that can be represented mathematically. This includes phenomena ranging from simple calculations to human thinking. A device able to make computations is called computational system.

Dynamical Recurrent Networks: Complex nonlinear dynamic system described by a set of nonlinear differential or difference equations with extensive connection weights.

Heteroclinic Orbits: In the phase portrait of a dynamical system, a heteroclinic orbit (sometimes called a heteroclinic connection) is a path in phase space which joins two different equilibrium points. If the equilibrium points at the start and end of the orbit are the same, the orbit is a homoclinic orbit.

Stability-Plasticity Dilemma: It explores how a learning system remains adaptive (plastic) in response to significant input, yet remains stable in response to irrelevant input.

Winnerless Competition Process: Dynamical process whose main point is the transformation of the incoming identity or spatial inputs into identity-temporal output based on the intrinsic switching dynamics of the neural system.

Biometric Security Technology

Marcos Faundez-Zanuy

Escola Universitària Politècnica de Mataró, Spain

INTRODUCTION

The word biometrics comes from the Greek words “bios” (life) and “metrikos” (measure). Strictly speaking, it refers to a science involving the statistical analysis of biological characteristics. Thus, we should refer to biometric recognition of people, as those security applications that analyze human characteristics for identity verification or identification. However, we will use the short term “biometrics” to refer to “biometric recognition of people”.

Biometric recognition offers a promising approach for security applications, with some advantages over the classical methods, which depend on something you have (key, card, etc.), or something you know (password, **PIN**, etc.). A nice property of biometric traits is that they are based on something you are or something you do, so you do not need to remember anything neither to hold any token.

Authentication methods by means of biometrics are a particular portion of security systems, with a good number of advantages over classical methods. However, there are also drawbacks (see Table 1).

Depending on the application, one of the previous methods, or a combination of them, will be the most appropriate. This article describes the main issues to be known for decision making, when trying to adopt a biometric security technology solution.

MAIN FOCUS OF THE ARTICLE

This article presents an overview of the main topics related to biometric security technology, with the central purpose to provide a primer on this subject.

Biometrics can offer greater security and convenience than traditional methods for people recognition. Even if we do not want to replace a classic method

Table 1. Advantages and drawbacks of the three main authentication method approaches

| Authentication method | Advantages | Drawbacks |
|--|--|--|
| Handheld tokens (card, ID, passport, etc.) | <ul style="list-style-type: none"> A new one can be issued. It is quite standard, although moving to a different country, facility, etc. | <ul style="list-style-type: none"> It can be stolen. A fake one can be issued. It can be shared. One person can be registered with different identities. |
| Knowledge based (password, PIN, etc.) | <ul style="list-style-type: none"> It is a simple and economical method. If there are problems, it can be replaced by a new one quite easily. | <ul style="list-style-type: none"> It can be guessed or cracked. Good passwords are difficult to remember. It can be shared. One person can be registered with different identities. |
| Biometrics | <ul style="list-style-type: none"> It cannot be lost, forgotten, guessed, stolen, shared, etc. It is quite easy to check if one person has several identities. It can provide a greater degree of security than the other ones. | <ul style="list-style-type: none"> In some cases a fake one can be issued. It is neither replaceable nor secret. If a person's biometric data is stolen, it is not possible to replace it. |

(password or handheld token) by a biometric one, for sure, we are potential users of these systems, which will even be mandatory for new passport models. For this reason, it is useful to be familiarized with the possibilities of biometric security technology.

BIOMETRIC TRAITS

The first question is: Which characteristic can be used for biometric recognition? As common sense says, a good biometric trait must accomplish a set of properties. Mainly they are (Clarke, 1994), (Mansfield & Wayman, 2002):

- Universality: Every person should have the characteristic.
- Distinctiveness: Any two persons should be different enough to distinguish each other based on this characteristic.
- Permanence: the characteristic should be stable enough (with respect to the matching criterion) along time, different environment conditions, etc.
- Collectability: the characteristic should be acquirable and quantitatively measurable.
- Acceptability: people should be willing to accept the biometric system, and do not feel that it is annoying, invasive, etc.
- Performance: the identification accuracy and required time for a successful recognition must be reasonably good.
- Circumvention: the ability of fraudulent people and techniques to fool the biometric system should be negligible.

Biometric traits can be split into two main categories:

- Physiological biometrics: it is based on direct measurements of a part of the human body. Fingerprint (Maltoni et al., 2003), face, iris and hand-scan (Faundez-Zanuy, Navarro-Mérida, 2005) recognition belong to this group.
- Behavioral biometrics: it is based on measurements and data derived from an action performed by the user, and thus indirectly measures some characteristics of the human body. Signature

(Faundez-Zanuy, 2005c), gait, gesture and key stroking recognition belong to this group.

However, this classification is quite artificial. For instance, the speech signal (Faundez-Zanuy and Monte, 2005) depends on behavioral traits such as semantics, diction, pronunciation, idiosyncrasy, etc. (related to socio-economic status, education, place of birth, etc.) (Furui, 1989). However, it also depends on the speaker's physiology, such as the shape of the vocal tract. On the other hand, physiological traits are also influenced by user behavior, such as the manner in which a user presents a finger, looks at a camera, etc.

Verification and Identification

Biometric systems can be operated in two modes, named identification and verification. We will refer to recognition for the general case, when we do not want to differentiate between them. However, some authors consider recognition and identification synonymous.

- Identification: In this approach no identity is claimed from the user. The automatic system must determine who the user is. If he/ she belongs to a predefined set of known users, it is referred to as closed-set identification. However, for sure the set of users known (learnt) by the system is much smaller than the potential number of people that can attempt to enter. The more general situation where the system has to manage with users that perhaps are not modeled inside the database is referred to as open-set identification. Adding a "none-of-the-above" option to closed-set identification gives open-set identification. The system performance can be evaluated using an identification rate.
- Verification: In this approach the goal of the system is to determine whether the person is the one that claims to be. This implies that the user must provide an identity and the system just accepts or rejects the users according to a successful or unsuccessful verification. Sometimes this operation mode is named authentication or detection. The system performance can be evaluated using the False Acceptance Rate (FAR, those situations where an impostor is accepted) and the False Rejection Rate (FRR, those situations where a user is incorrectly rejected), also known in detection

Figure 1. On the left: example of a DET plot for a user verification system (dotted line). The Equal Error Rate (EER) line shows the situation where False Alarm equals Miss Probability (balanced performance). Of course one of both errors rates can be more important (high security application versus those where we do not want to annoy the user with a high rejection/ miss rate). If the system curve is moved towards the origin, smaller error rates are achieved (better performance). If the decision threshold is reduced, higher False Acceptance/Alarm rates are achieved. On the right: Example of a ROC plot for a user verification system (dotted line). The Equal Error Rate (EER) line shows the situation where False Alarm equals Miss Probability (balanced performance).

theory as False Alarm and Miss, respectively. There is a trade-off between both errors, which has to be usually established by adjusting a decision threshold. The performance can be plotted in a **ROC** (Receiver Operator Characteristic) or in a **DET** (Detection error trade-off) plot (Martin et al., 1989). DET curve gives uniform treatment to both types of error, and uses a logarithmic scale for both axes, which spreads out the plot and better distinguishes different well performing systems and usually produces plots that are close to linear. Note also that the ROC curve has symmetry with respect to the DET, i.e. plots the hit rate instead of the miss probability. DET plot uses a logarithmic scale that expands the extreme parts of the curve, which are the parts that give the most information about the system performance. Figure 1, on the left shows an example of DET of plot, and on the right shows a classical ROC plot.

For systems working in verification mode, the evolution of FAR and FRR versus the threshold setting is an interesting plot. Using a high threshold, no impostor can fool the system, but a lot of genuine users will be rejected. Contrarily, using a low threshold, there would

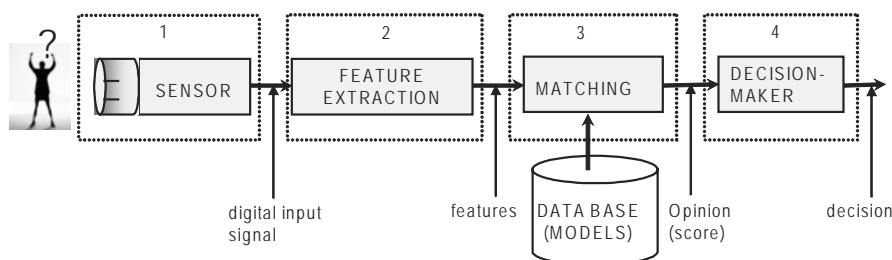

not be inconveniences for the genuine users, but it will be reasonably easy for a hacker to crack the system. According to security requirements, one of both taxes will be more important than the other one.

Is Identification Mode More Appropriate Than Verification Mode?

Certain applications lend themselves to verification, such as PC and network security, where, for instance, you replace your **password** by your fingerprint, but you still use your login. However, in forensic applications it is mandatory to use identification, because, for instance, latent prints lifted from crime scenes never provide their “claimed identity”.

In some cases, such as room access (Faundez-Zanuy, 2004c), (Faundez-Zanuy & Fabregas 2005), it can be more convenient for the user to operate on identification mode. However, verification systems are faster because they just require one-to-one comparison (identification requires one to N, where N is the number of users in the database). In addition, verification systems also provide higher accuracies. For instance, a hacker has almost N times (Maltoni & al., 2003) more chance to fool an

Figure 2. General scheme of a biometric recognition system

identification system than a verification one, because in identification he/she just needs to match one of the N genuine users. For this reason, commercial applications operating on identification mode are restricted to small-scale (at most, a few hundred users). Forensic systems (Faundez-Zanuy, 2005a), (Faundez-Zanuy, 2005b) operate in a different mode, because they provide a list of candidates, and a human supervisor checks the automatic result provided by the machine. This is related to the following classification, which is also associated to the application.

BIOMETRIC TECHNOLOGIES

Several biometric traits have been proven useful for biometric recognition. Nevertheless, the general scheme of a biometric recognition system is similar, in all the cases, to that shown in figure 2.

The scheme shown in figure 2 is also interesting for vulnerability study (Faundez-Zanuy, 2004b) and improvements by means of data fusion (Faundez-Zanuy, 2004d) analysis. In this paper, we will restrict to block number one, the other ones being related to signal processing and pattern recognition. Although common sense points out that good acquisition is enough for performing good recognition, at least for humans, this is not true. It must be taken into account that next blocks, numbered 2 to 4 in figure 2, are indeed fundamental. A good image or audio recording is not enough. Even for human beings, a rare disorder named **agnosia** exists. Those individuals suffering agnosia are unable to recognize and identify objects or persons despite having knowledge of the characteristics of the objects or persons. People with agnosia may have difficulty recognizing the geometric features of an object or face

or may be able to perceive the geometric features but do not know what the object is used for or whether a face is familiar or not. Agnosia can be limited to one sensory modality such as vision or hearing. A particular case is named face blindness or prosopagnosia (<http://www.faceblind.org/research>). Prosopagnosics often have difficulty recognizing family members, close friends, and even themselves. Agnosia can result from strokes, dementia, or other neurological disorders. More information about agnosia can be obtained from the National Organization for Rare Disorders (NORD <http://www.rarediseases.org>).

Table 2 summarizes some possibilities for different biometric traits acquisition. Obviously, properly speaking, some sensors require a digitizer connected at its output, which is beyond the scope of this paper. We will consider that block number one produces a digital signal which can be processed by a Digital Signal Processor (DSP) or Personal Computer (PC).

Figure 3 shows some biometric traits and their corresponding biometric scanners.

Security and Privacy

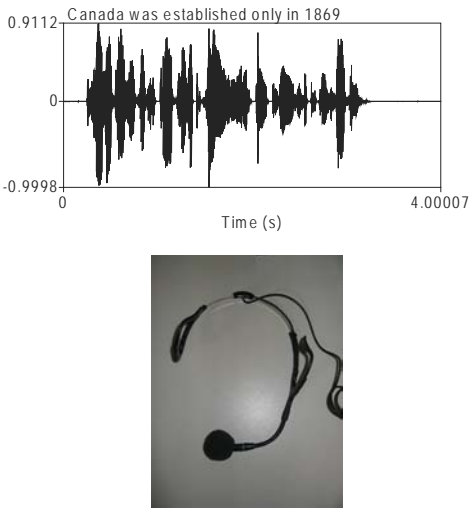

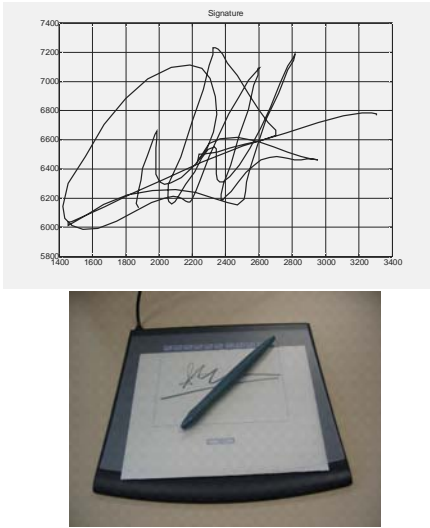

A nice property of biometric security systems is that security level is almost equal for all users in a system. This is not true for other security technologies. For instance, in an access control based on **password**, a hacker just needs to break only one password among those of all employees to gain access. In this case, a weak password compromises the overall security of every system that user has access to. Thus, the entire system's security is only as good as the weakest password (Prabhakar, Pankanti & Jain, 2003). This is especially important because good passwords are nonsense combinations of characters and letters, which

Table 2. Some biometric traits and possible acquisition sensors

| Biometric trait | Sensor | Comments |
|-----------------|-----------------------------------|---|
| Fingerprint | Ink+ paper + scanner | Classical method is becoming old-fashion, because the ink is annoying. However, it can acquire from nail to nail borders, and the other methods provide a limited portion of the fingerprint. |
| | Optical | It is the most widely used and easy-to-operate technology. It can acquire larger surfaces than the capacitive ones. |
| | Capacitive | They are easy to integrate into small, low-power and, low-cost devices. However, they are more difficult to operate than the optical ones (wet and/or warm fingers). |
| | Ultrasound | They are not ready for mass-market applications yet. However, they are more capable of penetrating dirt than the other ones, and are not subject to some of the image-dissolution problems found in larger optical devices. |
| Face | Photo-camera | Nowadays almost all the mobile phones have a photo-camera, enabling face recognition applications. |
| | Video-camera | A sequence of images alleviates some problems, such as face detection and offers more possibilities. |
| Speech | Microphone | The telephone system provides a ubiquitous network of sensors for acquiring speech signals. |
| Iris | Kiosk-based systems | The camera searches for eye position. They are the most expensive ones and the easier to operate. |
| | Physical access devices | The device requires some user effort: a camera is mounted behind a mirror. The user must locate the image of his eye within a 1-inch by 1-inch square surface on the mirror. |
| | Desktop cameras | The user must look into a hole and look at a ring illuminated inside. |
| Retina | Retina-scanner | A relative large and specialized device is required. It must be specifically designed for retina imaging. Image acquisition is not a trivial matter. |
| Signature | Ball pen + paper + scanner/camera | The system recognizes the signature analyzing its shape. This kind of recognition is known as “off-line”, while the other ones are “on-line”. |
| | Graphics tablet | It acquires the signature in real time. Some devices can acquire: position in x and y-axis, pressure applied by the pen, azimuth and altitude angles of the pen with respect to the tablet. |
| | PDA | Stylus operated PDAs are also possible. They are becoming more popular, so there are some potential applications. |
| Hand-geometry | Hand-scanning device | Commercial devices consist of a covered metal surface, with some pegs for ensuring the correct hand position. A series of cameras acquire three dimensional (3D) images of the back and the sides of the hand. |
| | Conventional scanner | Some research groups at universities have developed systems based on images acquired by a conventional document scanner. Thus, the cost is reduced, but the acquisition time is at least 15 seconds per image. |
| | Conventional camera | Some research groups at universities have developed systems based on images acquired by conventional cameras. Using some “bricolage” it is possible to obtain a 3D image. |
| Palm-print | Document scanner | Although there are not commercial applications, some research groups at universities have developed systems based on images acquired by a conventional document scanner. |
| Keystroke | keyboard | Although not used habitually, standard keyboards can measure how long keys are held down and duration between key instances, which is enough for recognition. |

Figure 3. Examples of biometric traits and an examples of commercial scanners

are difficult to remember (for instance, “Jh2pz6R+”). Unfortunately, some users still use passwords such as “password”, “Homer Simpson” or their own name.

FUTURE TRENDS

Although biometrics offers a good set of advantages, it has not been massively adopted yet (Faundez-Zanuy, 2005d). One of its main drawbacks is that biometric data is not secret and cannot be replaced after being compromised by a third party. For those applications with a human supervisor (such as border entrance control), this can be a minor problem, because the operator can check if the presented biometric trait is original or fake. However, for remote applications such as internet, some kind of liveness detection and **anti-replay attack** mechanisms should be provided. This is an emerging research topic. As a general rule, concerning security matters, a constant update is necessary in order to keep on being protected. A suitable system for the present time can become obsolete if it is not periodically improved. For this reason, nobody can claim that he/ she has a perfect security system, and even less that it will last forever.

Another interesting topic is privacy, which is beyond the scope of this article. It has been recently discussed in (Faundez-Zanuy, 2005a).

KEY TERMS

Automatic Identification: The system must determine who the user is.

Automatic Verification: The system must determine whether the person is the one that claims to be.

Behavioral Biometrics: Based on measurements and data derived from an action performed by the user, and thus indirectly measures some characteristics of the human body. Signature, gait, gesture and key stroking recognition belong to this group.

Equal Error Rate: System performance when False Acceptance Rate is identical to False Rejection Rate.

False Acceptance Rate: Ratio of impostors whose access is incorrectly permitted.

False Rejection Rate: Ratio of genuine users whose access is incorrectly denied.

Physiological Biometrics: Based on direct measurements of a part of the human body. Fingerprint, face, iris and hand-scan recognition belong to this group.

Blind Source Separation by ICA

Miguel A. Ferrer

University of Las Palmas de Gran Canaria, Spain

University of Las Palmas de Gran Canaria, Spain

INTRODUCTION

This work presents a brief introduction to the blind source separation using independent component analysis (ICA) techniques. The main objective of the blind source separation (BSS) is to obtain, from observations composed by different mixed signals, those different signals that compose them. This objective can be reached using two different techniques, the spatial and the statistical one. The first one is based on a microphone array and depends on the position and separation of them. It also uses the directions of arrival (DOA) from the different audio signals.

On the other hand, the statistical separation supposes that the signals are statistically independent, that they are mixed in a linear way and that it is possible to get the mixtures with the right sensors (Hyvärinen, Karhunen & Oja, 2001) (Parra, 2002).

The last technique is the one that is going to be studied in this work. It is due to this technique is the newest and is in a continuous development. It is used in different fields such as natural language processing (Murata, Ikeda & Ziehe, 2001) (Saruwatari, Kawamura & Shikano, 2001), bioinformatics, image processing (Cichocki & Amari, 2002) and in different real life applications such as mobile communications (Saruwatari, Sawai, Lee, Kawamura, Sakata & Shikano, 2003).

Specifically, the technique that is going to be used is the Independent Component Analysis (ICA). ICA comes from an old technique called PCA (Principal Component Analysis) (Hyvärinen, Karhunen & Oja, 2001) (Smith, 2006). PCA is used in a wide range of scopes such as face recognition or image compression, being a very common technique to find patterns in high dimension data.

The BSS problem can be of two different ways; the first one is when the mixtures are linear. It means that the data are mixed without echoes or reverberations, while the second one, due to these conditions, the mixtures are convolutive and they are not totally independent

because of the signal propagation through dynamic environments. It is the “Cocktail party problem”. Depending on the mixtures, there are several methods to solve the BSS problem. The first case can be seen as a simplification of the second one.

The blind source separation based on ICA is also divided into three groups; the first one are those methods that works in the time domain, the second are those who works in the frequency domain and the last group are those methods that combine frequency and time domain methods. A revision of the technique state of these methods is proposed in this work.

BACKGROUND

The problem consists in several sources that are mixed in a system, these mixtures are recorded and then they have to be separated to obtain the estimations of the original sources. As was mentioned above, BSS problems can be of two different types; the first one, when the mixtures are linear, see equation 3, and the second one, when the mixtures are convolutive, see equation 5.

In the first case each source signal is multiplied by a constant which depends on the environment, and then they are added. Convolutive mixtures are not totally independent due to the signal propagation through dynamic environments. This makes that the signals are not simply added. The first case is the ideal one, and the second is the most common case, because in real room recordings the mixing systems are of this type. The following figure shows the mixing system in the case of two sources two mixtures:

Where X_1 and X_2 are the independent signals, Y_1 and Y_2 are the mixing of the different X_j , and \bar{H} is the mixing system that can be seen in a general form as:

Figure 1. 2 sources – 2 mixtures system.

$$\overline{H} = \begin{bmatrix} h_{11} & \dots & h_{1j} \\ \dots & \dots & \dots \\ h_{i1} & \dots & h_{ij} \end{bmatrix} \quad (1)$$

The h_{ij} are FIR filters, each one represents an acoustic transference multipath function from source, i , to sensor, j . i and j represent the number of sources and sensors. Now it is necessary to remember the first condition that makes possible the blind source separation:

“The number of sensors must be greater than or equal to the number of sources.”

Taking this into account, the problem for two sensors, in a general form, can be represented as:

$$Y_1 = X_1 * h_{11} + X_2 * h_{12} \quad (2.1)$$

$$Y_2 = X_1 * h_{21} + X_2 * h_{22} \quad (2.2)$$

Generally, there are n source signals statistically independent $X(t) = [X_1(t), \dots, X_n(t)]$, and m observed mixtures that are linear and instantaneous combinations of the previous signals $Y(t) = [Y_1(t), \dots, Y_m(t)]$. Beginning with the linear case, the simplest case, the mixtures are:

$$Y_i(t) = \sum_{j=1}^n h_{ij} \cdot X_j(t) \quad (3)$$

Now, we need to recover $X(t)$ from $Y(t)$. It is necessary to estimate the inverse matrix of H , where h_{ij} are contained. Once we have this matrix:

$$\hat{X}(t) = \overline{W} \cdot Y(t) \quad (4)$$

where $\hat{X}(t)$ contains the estimations of the original source signals, and \overline{W} is the inverse mixing matrix. Now we have defined the simplest case, it is time to explain the general case that involves convolutive mixtures.

The whole process, which includes mixing and separation process, and that has been described before for linear mixtures, is defined as in Figure 2.

The process will be the following; first a set of source signals (X) pass through an unknown system \overline{H} . The output (Y) contains all the mixtures. Y is equalized with an inverse estimated system \overline{W} , which has to give an estimation of the original source signals (\hat{X}).

Given access to N sensors with a number of sources less than or equal to N , all with unknown direct and cross channels, the objective is to recover all the unknown sources. Here arises the second condition to obtain the source separation:

“In blind source separation using ICA, it is assumed that we only know the probability density functions of the non-Gaussian and independent sources.”

So we have to obtain \overline{W} , and it must be that:

$$\hat{X} = \overline{W} * Y \quad (5)$$

Here, as it was mentioned above, \hat{X} are the estimations of the original source signals, Y are the observations, and \overline{W} is the inverse mixing filter.

BLIND SOURCE SEPARATION BY ICA

This article presents different methods to solve the blind source separation, more exactly those that are based on independent component analysis (ICA). First, methods for the linear mixtures are going to be described, and then we are going to divide the methods for convolutive mixtures in three groups depending on the domain; frequency domain, time domain or both.

Blind Source Separation for Linear Mixtures

The blind source separation for linear mixtures is a particular case of the convolutive one. So methods

Figure 2. BSS general problem

designed for convolutive mixtures must solve the problem of the linear mixtures in theory. In this case, we have decided to describe some linear methods separately due to there being some important methods specialized in this case.

There are different methods such as Infomax, which is based on the maximization of the information (Bell & Sejnowski, 1995), the one based on minimization of the mutual information (Hyvärinen, Karhunen & Oja, 2001), or methods which use tensors. The methods that are going to be described in this paper are FastICA and JADE, they have been selected due to they are two of the most famous methods for the linear case of BSS, and because they are a right first step into the BSS.

The first one, and maybe the most known, is FastICA (Hyvärinen, Karhunen & Oja, 2001). The FastICA algorithm is a computationally highly efficient method for performing the estimation of ICA. It uses a fixed-point iteration scheme that has been found in independent experiments to be 10-100 times faster than conventional gradient descent methods for ICA. Another advantage of the FastICA algorithm is that it can be used to perform projection pursuit as well, thus providing a general-purpose data analysis method that can be used both in an exploratory fashion and for estimation of independent components (or sources) (Hyvärinen, Karhunen & Oja, 2001) (Parra, 2002). This algorithm is available in a toolbox that is very easy to use (Helsinki University of Technology, 2006).

Another method that is very common in blind source separation of linear mixtures is JADE (Cardoso, 1993) (Hyvärinen, Karhunen & Oja, 2001). JADE (Join approximate diagonalization of eigenmatrices) refers to one principle of solving the problem of equal eigenvalues of the cumulant tensor. In this algorithm, the tensor EVD is considered more as a preprocessing step. A method closely related to JADE is given by the eigenvalue decomposition of the weighted correlation

matrix. For historical reasons, the basic method is simply called fourth-order blind identification (FOBI) (Hyvärinen, Karhunen & Oja, 2001).

Blind Source Separation for Convolutive Mixtures

Once the linear problem has been described, it is time to explain how to solve the problem with convolutive mixtures. This case is more complex than the linear one, as was presented in the Background. When the mixtures are convolutive the problem is also called blind deconvolution.

To solve this problem, several methods have been designed. They can be divided into three groups depending on the domain: time domain, frequency domain or both.

When the algorithm works in the frequency domain, the convolutive mixtures can be simplified into simultaneous ones by means of the frequency transform. This makes easier the convergence of the separation filter (Choi, Cichocki, Park & Lee, 2005). So these algorithms can increase the speed of convergence and reduce the computational load. But it has a cost; to maintain the computational efficiency these algorithms need to increase the length of the frame when the window frame increases. The data is reduced and can provoke insufficiency of the learning data. So the efficiency of the algorithm is degraded.

Some examples of these algorithms are: blind source separation in the wavelet domain, recursive method (Ding, Hikichi, Niitsuma, Hamatsu & Sugai, 2003), time delay decorrelation (Lee, Ziehe, Orglmeister & Sejnowski, 1998), ICA algorithm and beamforming (Saruwatari, Kawamura & Shikano, 2001) or the FIR matrix toolbox 5.0 (Lambert, 1996).

If the algorithm works in the time domain, we can work with wide band audio signals, where the assump-

tion of independence is kept. The disadvantages are that they produce a high computational load when they work with huge separation matrixes, and the convergence is slow, overall when the signals are voices.

Some algorithms that work in time domain are SIMO – ICA (Saruwatari, Sawai, Lee, Kawamura, Sakata & Shikano, 2003), filter banks (Choi, Cichocki, Park & Lee, 2005) or time-domain fast fixed-point algorithms for convolutive ICA (Thomas, Deville & Hosseini, 2006).

But we can also combine the two previous methods to compensate the advantages and disadvantages of each other, for example in Multistage ICA (Nishikawa, Saruwatari, Shikano, Araki & Makino, 2003); FDICA (frequency domain ICA) and TDICA (time domain ICA) are combined with the objective of attaining better efficiency that is possible. This algorithm has a stable behaviour, but the computational load is high.

FUTURE TRENDS

Blind source separation has wide scope that is in continuous development and several authors are working on the design or modification of different methods. In this work, different algorithms have been presented to solve the blind source separation problem.

Future trends will be the design of on line methods that allow the implementation of these algorithms in real life applications such as voice recognition or free hand devices. The algorithms can also be improved with the aim of reaching more efficient and accurate separation of the mixtures, linear or convolutive. It will help in different systems as a first step for identifying speakers, for example in conferences, videoconferences or similar.

CONCLUSION

This article shows different ways to solve blind source separation. It also illustrates that the problem can be of two forms depending on the mixtures. If we have linear mixtures the system will have a different behaviour that if we have convolutive ones.

As has been described above, the methods can be also divided into two types, the frequency domain and the time domain algorithms. The first type has a faster convergence than the time domain type, but

it can work incorrectly if data are insufficient. Time domain methods have more stable behaviour than the frequency algorithms, but a higher computational load. To trade off the advantages with the disadvantages of each type of method, multistage algorithms have been proposed.

KEY TERMS

Blind Source Separation: The problem of separating from mixtures, the source signals that compose them.

Cocktail Party Problem: A particular case of blind source separation where the mixtures are convolutive.

Convolutive Mixtures: Mixtures that are not linear due to echoes and reverberations, they are not totally independent because of the signal propagation through dynamic environments.

HOS (High Order Statistics): Higher order statistics is a field of statistical signal processing that uses more information than autocorrelation functions and spectrum. It uses moments, cumulants and polyspectra. They can be used to get better estimates of parameters in noisy situations, or to detect nonlinearities in the signals.

ICA (Independent Component Analysis): Techniques based on statistical concepts such as high order statistics.

Linear mixtures: Mixtures that are linear combinations of the different sources that compose them.

Statistically Independent: Given two events, the occurrence of one event makes it neither more nor less probable that the other occurs.

Chaotic Neural Networks

Emilio Del-Moral-Hernandez

University of São Paulo, Brazil

INTRODUCTION

Artificial Neural Networks have proven, along the last four decades, to be an important tool for modelling of the functional structures of the nervous system, as well as for the modelling of non-linear and adaptive systems in general, both biological and non biological (Haykin, 1999). They also became a powerful biologically inspired general computing framework, particularly important for solving non-linear problems with reduced formalization and structure. At the same time, methods from the area of complex systems and non-linear dynamics have shown to be useful in the understanding of phenomena in brain activity and nervous system activity in general (Freeman, 1992; Kelso, 1995). Joining these two areas, the development of artificial neural networks employing rich dynamics is a growing subject in both arenas, theory and practice. In particular, model neurons with rich bifurcation and chaotic dynamics have been developed in recent decades, for the modelling of complex phenomena in biology as well as for the application in neuro-like computing. Some models that deserve attention in this context are those developed by Kazuyuki Aihara (1990), Nagumo and Sato (1972), Walter Freeman (1992), K. Kaneko (2001), and Nabil Farhat (1994), among others. The following topics develop the subject of Chaotic Neural Networks, presenting several of the important models of this class and briefly discussing associated tools of analysis and typical target applications.

BACKGROUND

Artificial Neural Networks (ANNs) is one of the important frameworks for biologically inspired computing. A central characteristic in this paradigm is the desire to bring to computing models some of the interesting properties of the nervous system such as adaptation, robustness, non-linearity, and the learning through examples.

When we focus on biology (real neural networks), we see that the signals generated in real neurons are used in different ways by the nervous system to code information, according to the context and the functionality (Freeman, 1992). Because of that, in ANNs we have distinct model neurons, such as models with graded activity based on frequency coding, models with binary outputs, and spiking models (or pulsed models), among others, each one giving emphasis to different aspects of neural coding and neural processing. Under this scenario, the role of neurodynamics is one of the target aspects in neural modelling and neuro-inspired computing; some model neurons include aspects of neurodynamics, which are mathematically represented through differential equations in continuous time, or difference equations in discrete time. As described in the following topic, dynamic phenomena happen at several levels in neural activity and neural assembly activity (in internal neural structures, in simple networks of interacting neurons, and in large populations of neurons). The model neurons particularly important for our discussion are those that emphasize the relationship between neurocomputing and non-linear dynamical systems with bifurcation and rich dynamic behaviour, including chaotic dynamics.

NEUROCOMPUTING AND THE ROLE OF RICH DYNAMICS

The presence of dynamics in neural functionality happens even at the more detailed cellular level: the well known Hodgkin and Huxley model for the generation and propagation of action potentials in the active membrane of real neurons is an example; time dependent processes related to synaptic activity and the post synaptic signals is another example. Dynamics also appears when we consider the oscillatory behaviour in real neurons under consistent stimulation. Additionally, when we consider neural assemblies, we also observe the emergence of important global dynamic behaviour for the production of complex functions.

As discussed ahead, non-linearity is an essential ingredient for complex functionality and for complex dynamics; there is a clear contrast between linear dynamic systems and non-linear dynamic systems, in what respect their potential for the production of rich and diverse behaviour.

Role of Non-Linear Dynamics in the Production of Rich Behaviour

In linear dynamical systems, both in continuous time and in discrete time, the autonomous dynamical behaviour is completely characterized through the system's natural modes, either the harmonic oscillatory modes, or the exponentially decaying modes (in the theory of linear dynamical systems, these are represented by frequencies and complex frequencies). The possible dynamic outcomes in linear systems are thus limited to the universe of linear combinations of these natural modes. These modes can have their properties of amplitudes and frequencies controlled through parameters of the system, but not their central properties such as the nature of the produced waveforms. Since the number of natural modes of linear systems is closely related to the number of state variables, we have that small networks (of linear dynamic elements) can produce only limited diversity of dynamical behaviour.

The scenario becomes completely different in non-linear systems. Non-linearity promotes rich dynamic behaviour, obtained by changing the stability and instability of different attractors. These changes give place to bifurcation phenomena (transitions between dynamic modalities with distinct characteristics) and therefore to diversity of dynamic behaviour. In non-linear systems, we can have a large diversity of dynamical behaviours, with the potential production of infinite number of distinct waveforms (or time series, for discrete time systems). This can happen for systems with very reduced number of state variables: just three in continuous time, or just one state variable in discrete time, are enough to allow bifurcation among different attractors and potential cascades of infinite bifurcations leading to chaos. In our context, this means obtaining rich attractor behaviour even from very simple neural networks (i.e., networks with a small number of neurons).

In summary, the operation of chaotic neural networks explores the concepts of attractors, repellers, limit cycles, and stability (see the topic Terms and

Definitions for details on these concepts) of trajectories in the multidimensional state space of the neural network, and more specifically, the dense production of destabilization of cyclic trajectories with cascading to chaotic behaviour. This scenario allows for the blend of ordered behaviour and chaotic dynamics, and the presence of fractal structure and self-similarity in the rich landscape of dynamic attractors.

MODEL NEURONS WITH RICH DYNAMICS, BIFURCATION AND CHAOS

We can look at chaotic elements that compose neuro-like architectures from several different perspectives. They can be looked at as emergent units with rich dynamics that are produced by the interaction of classical model neurons, such as the sigmoidal model neurons based on frequency coding (Haykin, 1999), or the integrate and fire spiking model neurons (Farhat, 1994). They can also correspond to the modelling of dynamical behaviour of neural assemblies, approached as a unity (Freeman, 1992). Finally, they can be tools for approximate representation of aspects of complex dynamics in the nervous system, paying attention mainly to the richness of attractors and blend of ordered and erratic dynamics, and not exactly to the details of the biological dynamics (DelMoral, 2005; Kaneko, 2001). Ahead we describe briefly some of the relevant model neurons in the context of chaotic neural networks.

Aihara's Chaotic Model Neuron. One important work in the context of chaotic neural networks is the model neuron proposed by Kazuyuki Aihara and collaborators (1990). In it, we have self-feedback of the neuron's state variable, for representing the refractory period in real neurons. This makes possible rich bifurcation and cascading to chaos. His work extends previous models in which some elements of dynamics were already present. In particular, we have to mention the work by Caianiello (1961), in which the past inputs have impact on the value of the present state of the neuron, and the work by Nagumo and Sato (1972), which incorporates an exponential decay memory. Aihara's model included memory for the inputs of the model neuron as well as for its internal state. It also included continuous transfer functions, an essential ingredient for rich bifurcation, fractal structure and cascading to chaos. Equation 1 shows a simplified form

of this model: x_i is the node state, while the x_j regard neighboring nodes, t is discrete time, f a continuous function, k_f and k_r decay constants, and w_{ij} generic coupling strengths:

$$x_i(t+1) = f\left(\sum_{j=1}^M w_{ij} \sum_{d=0}^t k_f^d x_j(t-d) - \alpha \sum_{d=0}^t k_r^d x_i(t-d)\right) \quad (1)$$

Adachi's Associative Memory. Another proposal that can be mentioned here is that of Adachi, co-authored with Aihara. It uses Aihara's chaotic neuron for the implementation of associative memories, with coupling strengths among nodes, w_{ij} , given by Hebbian-like correlation measures (Adachi, 1997). Equation 2 defines w_{ij} for this model, in a memory storing M binary strings x^p .

$$w_{ij} = \sum_{p=1}^M (x_i^p - \bar{x})(x_j^p - \bar{x}) \quad (2)$$

Nabil Farhat's Bifurcating Neuron. Nabil Farhat and collaborators introduced the "Bifurcation Neuron", in which the phenomena of bifurcation and cascade to chaotic dynamics emerge from a pulsed model of type "Integrate and Fire" (Farhat, 1994). This work and some of its following developments have direct relationship to a class of association and pattern recovery architectures developed by the author of this

article: chaotic neural networks based on **Recursive Processing Elements**, or **RPEs** (DelMoral, 2005 ; DelMoral, 2007). RPEs are parametric recursions that are coupled through modulation of their bifurcation parameters (we say we have *parametric coupling*), for the formation of meaningful collective patterns. Node dynamics is mathematically defined through a first order parametric recursion:

$$x(t+1) = R_p(x(t)) \quad (3a)$$

$$\text{example: } x(t+1) = p \cdot [x(t) \cdot (1-x(t))] \quad (3b)$$

This recursion R_p (parameterized by the "bifurcation parameter" p) links consecutive values of the state variable x , which evolves in discrete time t . It is interesting to comment that first order non-linear recursions are very simple mathematical systems with very rich dynamical behavior (Fig.1 shows an illustrative bifurcation diagram).

Kunihiro Kaneko's Coupled Map Lattices - CMLs. These structures, initially conceived for the modelling of spatio-temporal physical systems, employ the idea of chaotic recursive maps (similar to the RPEs above described) that interact through diffusive-like coupling (Kaneko, 2001). Equation 4 represents a CML: i identifies a node of a linear lattice, and ε the amount of coupling.

Figure 1. Bifurcation diagram for the logistic recursion, where $R_p(x) = p \cdot x \cdot (1-x)$

$$x_i(t+1) = (1-\varepsilon).R_p(x_i(t)) + \frac{\varepsilon}{2}.R_p(x_{i-1}(t)) + \frac{\varepsilon}{2}.R_p(x_{i+1}(t)) \quad (4)$$

Non-Linear Dynamics Tools

The classical tools developed for the study of non-linear dynamic systems with bifurcation and diverse behaviour (Hilborn, 1994) are important elements in the study and characterization of chaotic neural networks (Kaneko, 2001 ; DelMoral, 2007). Among the important ones, we can mention the Bifurcation Diagrams (see Fig.1), which are useful for the representation of the long-term behavior in parametric non-linear dynamical systems, as well as for the representation of their bifurcations and their parameter ranges for ordered behavior and chaotic behavior. We can also mention the Lyapunov exponents, for the quantitative evaluation of sensibility to initial conditions, the Entropy measures, for the quantification of trajectory complexity, the Return Maps, for the characterization of recursive rules, and the Web Diagrams, for the illustration of attractor and repeller trajectories (Hilborn, 1994 ; Devaney, 1989 ; Kaneko, 2001).

COLLECTIVE DYNAMIC BEHAVIOUR, ATTRACTOR NETWORKS AND APPLICATION SCENARIOS

A more complex and richer scenario can be created through the coupling of several units having rich dynamic behavior at the single node level. The following paragraphs detail some of the emergent collective phenomena that appear in networks of coupled chaotic elements and are explored for information coding and processing:

- **Multidimensional attractors.** In the multidimensional attractor behavior, similarly to attractors at the single node level (see entry in the topic Terms and Definitions, at the end of this article), we have the evolution in time of the network state towards a limited repertoire of preferential collective trajectories, which emerge in the long-term. The concept of Multidimensional Attractors is central to the *Attractor Networks* paradigm: high dimen-

sional dynamical systems whose long-term states represent relevant information. In the particular case of chaotic neural networks, the evolution of the network state is usually composed by an initial chaotic phase and a gradual approximation to ordered limit cycles (Kaneko, 2001 ; DelMoral, 2005 ; Freeman, 1992).

- **Clustering of nodes' activities.** Here we have, due to coupling and network self organization, the formation of groups of nodes exhibiting activities which are identical or similar in some sense (Kaneko, 2001).
- **Synchronization of the nodes' cycling** (or phase locking). In this type of collective phenomena, which is a particular case of clustering, the cyclic activities of nodes belonging to a cluster have the same period, and they operate with constant relative phases (DelMoral, 2005 ; DelMoral, 2007).

With collective structures (multiple coupled neurons), complex functionalities can potentially be implemented, through the exploration of the multidimensional nature of the state variables: image understanding, processing of multiple sensory information, multidimensional logical reasoning, complex motor control, memory, association, hetero-association, decision making and pattern recognition (DelMoral, 2007). In networks of coupled elements with rich dynamics, the above collective phenomena are explored for the representation and processing of meaningful information. A stored memory, in association and pattern recovery tasks, or a class label, in pattern recognition tasks, for example, can be represented through the specific collective attractors of the network (DelMoral, 2005). Concretely, the representation of information can happen through different quantitative features of the relevant attractors. We can have the coding of analog information through the amplitude of oscillations of the state variables, or even through the sequences of values visited by the state variables in limit cycles. We can also have the coding of class labels through the periods of closed trajectories, through the phase of cycling of closed trajectories, or even through mixed forms involving several of these coding modalities. In addition, clustering and synchronization can be used for spatial segmentation of information.

Blend of Order and Complex Dynamics

A macroscopic phenomenon that relates to the global behavior of a coupled structure composed of several neurons with rich dynamics (as the models described in previous topics) is the interplay between ordered behavior and disordered behavior. In many circumstances, we can look at the network's state evolution as switching between situations of ordered behavior and situations of apparently erratic behavior. The blend of ordered and erratic behaviour is explored for the representation of meaningful information (order) and the rich search in the state space for stored patterns (chaotic search).

This blend of ordered and erratic behaviour appears in many different classes of model neurons and associated architectures, such as for example, the Bifurcation Neuron, K Sets structures, RPEs architectures and many others.

FUTURE TRENDS

Since chaotic neural networks are a relatively recent subject of research, there are many different directions in which the field can potentially progress. We will just mention some of these directions.

An important possibility that we can identify is the exploration of rich dynamics, fractal structure and diversity of dynamical behaviour, in the modelling and emulation of higher cognitive functions. We can mention for example that part of the current research on consciousness and cognition addresses the possible roles of complex dynamics on these high level functions (Perlovsky & Kozma, 2007).

We also see spiking model neurons, a fast growing research area, and neural oscillators as natural scenarios for the emergence of rich dynamic phenomena and as potential substrates for computing with rich dynamics (Gerstner, 2002). We add that there are several efforts for the implementation of spiking models in electronic form (DelMoral, 2003); these efforts can also have an important role in the context of brain-computer interfaces based on microelectrode arrays and associated electronics, another fast growing research area.

CONCLUSION

Chaotic Neural Networks and the associated chaotic model neurons discussed here are part of a current trend in neural modelling and artificial neurocomputing that moves the emphasis of artificial model neurons, from functional analysis and functional synthesis, particularly evident in neural architectures such as the MLPs, to a more balanced blend which involves also elements of neurodynamics and explores extensively the paradigm of attractor networks. With this ongoing move, the tendency is to have more powerful modelling tools for the study of the nervous system and more powerful elements for the development of neuro-like computing environments.

KEY TERMS

Artificial Neurons/Model Neurons: Mathematical description of the biological neuron, in what respects representation and processing of information. These models are the processing elements that compose an artificial neural network. In the context of chaotic neural networks, these models include the representation of aspects of complex neurodynamics.

Attractors, Repellers and Limit Cycles: These three concepts are related to the concept of dynamic modality and they regard the long-term behaviour of a dynamical system. Attractors are trajectories of the system state variable that emerge in the long-term, with relative independence with respect to the exact values of the initial conditions. These long-term trajectories can be either a point in the state space (a static asymptotic behaviour), named fixed-point, a cyclic pattern (named limit cycle), or even a chaotic trajectory. Repellers correspond, qualitatively speaking, to the opposite behaviour of attractors: given a fixed-point or a cyclic trajectory of a dynamic system, they are called repeller-type trajectories if small perturbations can make the system evolve to trajectories that are far from the original one.

Bifurcation and Diverse Dynamics: The concept of bifurcation, present in the context of non-linear dynamic systems and theory of chaos, refers to the transition between two dynamic modalities qualitatively distinct; both of them are exhibited by the same dynamic system, and the transition (bifurcation) is promoted by the change in value of a relevant numeric parameter of such system. Such parameter is named “bifurcation parameter”, and in highly non-linear dynamic systems, its change can produce a large number of bifurcations between distinct dynamic modalities, with self-similarity and fractal structure. In many of these systems, we have a cascade of numberless bifurcations, culminating with the production of chaotic dynamics.

Chaotic Dynamics: Dynamics with specific features indicating complex behaviour, only produced in highly non-linear systems. These indicative features, formalized by the discipline of “Theory of Chaos”, are high sensibility to initial conditions, non-periodic behaviour, and production of a large number of different trajectories in the state space, according to the change of some meaningful parameter of the dynamical system

(see bifurcation and diverse dynamics ahead). For some of the tools related to chaotic dynamics, see the related topic in the main text: Non-linear dynamics tools.

Chaotic Model Neurons: Model neurons that incorporate aspects of complex dynamics observed either in the isolated biological neuron or in assemblies of several biological neurons. Some of the models with complex dynamics, mentioned in the main text of this article, are the Aihara's model neuron, the Bifurcation Neuron proposed by Nabil Farhat, RPEs networks, Kaneko's CMLs, and Walter Freeman's K Sets.

Spatio-Temporal Collective Patterns: The observed dynamic configurations of the collective state variable in a multi neuron arrangement (network). The temporal aspect comes from the fact that in chaotic neural networks the model neurons' states evolve in time. The spatial aspect comes from the fact that the neurons that compose the network can be viewed as sites of a discrete (grid-like) spatial structure.

Stability: The study of repellers and attractors is done through stability analysis, which quantifies how infinitesimal perturbations in a given trajectory performed by the system are either attenuated or amplified with time.

Class Prediction in Test Sets with Shifted Distributions

INTRODUCTION

Machine learning has provided powerful algorithms that automatically generate predictive models from experience. One specific technique is *supervised learning*, where the machine is trained to predict a desired output for each input pattern \mathbf{x} . This chapter will focus on *classification*, that is, supervised learning when the output to predict is a class label. For instance predicting whether a patient in a hospital will develop cancer or not. In this example, the class label c is a variable having two possible values, “cancer” or “no cancer”, and the input pattern \mathbf{x} is a vector containing patient data (e.g. age, gender, diet, smoking habits, etc.). In order to construct a proper predictive model, supervised learning methods require a set of examples \mathbf{x}_i together with their respective labels c_i . This dataset is called the “training set”. The constructed model is then used to predict the labels of a set of new cases \mathbf{x}_j called the “test set”. In the cancer prediction example, this is the phase when the model is used to predict cancer in new patients.

One common assumption in supervised learning algorithms is that the statistical structure of the training and test datasets are the same (Hastie, Tibshirani & Friedman, 2001). That is, the test set is assumed to have the same attribute distribution $p(\mathbf{x})$ and same class distribution $p(c|\mathbf{x})$ as the training set. However, this is not usually the case in real applications due to different reasons. For instance, in many problems the training dataset is obtained in a specific manner that differs from the way the test dataset will be generated later. Moreover, the nature of the problem may evolve in time. These phenomena cause $p^{\text{Tr}}(\mathbf{x}, c) \neq p^{\text{Test}}(\mathbf{x}, c)$, which can degrade the performance of the model constructed in training.

Here we present a new algorithm that allows to re-estimate a model constructed in training using the

unlabelled test patterns. We show the convergence properties of the algorithm and illustrate its performance with an artificial problem. Finally we demonstrate its strengths in a heart disease diagnosis problem where the training set is taken from a different hospital than the test set.

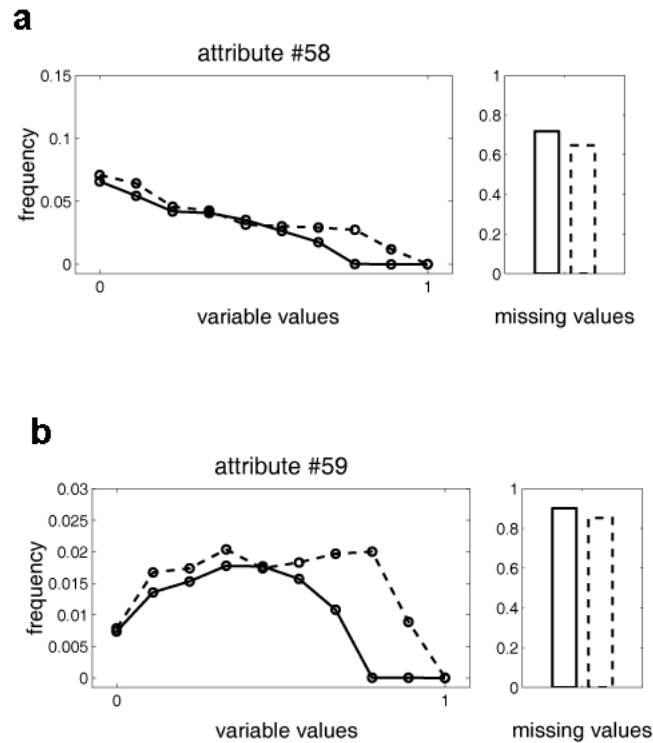

BACKGROUND

In practical problems, the statistical structure of training and test sets can be different, that is, $p^{\text{Tr}}(\mathbf{x}, c) \neq p^{\text{Test}}(\mathbf{x}, c)$. This effect can be caused by different reasons. For instance, due to biases in the sampling selection of the training set (Heckman, 1979; Salganicoff, 1997). Other possible cause is that training and test sets can be related to different contexts. For instance, a heart disease diagnosis model that is used in a hospital which is different from the hospital where the training dataset was collected. Then, if the hospitals are located in cities where people have different habits, average age, etc., this will cause a test set with a different statistical structure than the training set.

The special case $p^{\text{Tr}}(\mathbf{x}) \neq p^{\text{Test}}(\mathbf{x})$ and $p^{\text{Tr}}(c|\mathbf{x}) = p^{\text{Test}}(c|\mathbf{x})$ is known in the literature as “covariate shift” (Shimodaira, 2000). In the context of machine learning, the covariate shift can degrade the performance of standard machine learning algorithms. Different techniques have been proposed to deal with this problem, see for example (Heckman, 1979; Salganicoff, 1997; Shimodaira, 2000; Sugiyama, Krauledat & Müller, 2007). Transductive learning has also been suggested as another way to improve performance when the statistical structure of the test set is shifted with respect to the training set (Vapnik, 1998; Chen, Wang & Dong, 2003; Wu, Bennett, Cristianini & Shawe-Taylor, 1999).

The statistics of the patterns \mathbf{x} can also change in time, for example in a company that has a continuous

Figure 1. Changes across time of the statistics of clients in a car insurance company. The histograms of two different variables (a, b) related to the clients' use of their insurance are shown. Dash: data collected four months later than data shown in solid.

flow of new and leaving clients (figure 1). If we are interested in constructing a model for prediction, the statistics of the clients when the model is exploited will differ from the statistics in training. Finally, often the concept to be learned is not static but evolves in time (for example, predicting which emails are spam or not), causing $p^{\text{Tr}}(\mathbf{x}, c) \neq p^{\text{Test}}(\mathbf{x}, c)$. This problem is known as “concept drift” and different algorithms have been proposed to cope with it (Black & Hickey, 1999; Wang, Fan, Yu, & Han, 2003; Widmer & Kubat, 1996).

A NEW ALGORITHM FOR CONSTRUCTING CLASSIFIERS WHEN TRAINING AND TEST SETS HAVE DIFFERENT DISTRIBUTIONS

Here we present a new learning strategy for problems where the statistical distributions of the training and

test sets are different. This technique can be used in problems where concept drift, sampling biases, or any other phenomena exist that cause the statistical structure of the training and test sets to be different. On the other hand, our strategy constructs an explicit estimation of the statistical structure of the problem in the test data set. This allows us to construct a classifier that is optimized with respect to the new test statistics, and provides the user with relevant information about which aspects of the problem have changed.

Algorithm

1. Construct a statistical model $\{\tilde{P}(x|c), \tilde{P}(c)\}$ for the training set using a standard procedure (for example, using the standard EM algorithm).
2. Re-estimate this statistical model using the non-labelled patterns \mathbf{x} of the test set. For this purpose, we have developed a semi-supervised extension of EM.

- Use this re-estimated statistical model $\{\tilde{P}'(x|c), \tilde{P}'(c)\}$ to construct a classifier optimized to the test set.

Model Re-Estimation: A Semi-Supervised Extension of EM

The standard EM algorithm (Dempster, Laird & Rubin, 1977) is an iterative procedure designed to find the optimal parameters of a statistical model in a maximum likelihood sense. Here we present an extension of the EM algorithm that re-estimates the statistical model learned in training using the unlabelled test set, under the assumption that it should resemble the statistical model learned at training. That is, the algorithm finds the minimum amount of change that one has to assume for the model constructed in training (where we know the pattern classes) to explain the global distribution of attributes \mathbf{x} in the test set.

Let us call Θ the set of different parameters in the statistical model of our problem. For example, if we model $\tilde{P}(\mathbf{x}|c=1)$ and $\tilde{P}(\mathbf{x}|c=2)$ by a mixture of two and three Gaussians respectively, then Θ would be composed by the averages, covariance matrices and likelihoods of the 2+3 different Gaussians in the model. An estimation Θ_{Tr} should be first made in the training set using a standard technique such as applying EM for each individual class. Then, we should recalculate it as Θ_{Te} using the unlabelled test set by optimizing the likelihood $\tilde{P}(\Theta_{\text{Te}}|\mathcal{D}_{\text{Te}}, \Theta_{\text{Tr}})$ where \mathcal{D}_{Te} is the unlabelled test set (test patterns without the class information). The maximization of this quantity respect to Θ_{Te} is equivalent to maximizing the quantity

$$L' \equiv \ln \tilde{P}(\mathcal{D}_{\text{Te}}|\Theta_{\text{Te}}) + \ln \tilde{P}(\Theta_{\text{Te}}|\Theta_{\text{Tr}})$$

which we will call the “extended log-likelihood”. The term $\tilde{P}(\Theta_{\text{Te}}|\Theta_{\text{Tr}})$ implements the bias in the re-estimation of the parameters, which in our case is a preference for small changes. Using this extended log-likelihood it is possible to derive a new version of EM that maximizes L' .

To achieve it we consider, as in standard EM applications, the existence of additional but *latent* (or ‘hidden’) variables \mathbf{h} in the problem (Dempster, Laird & Rubin, 1977). For example, in case we model the statistics as a mixture of Gaussians, the latent variable

indicates which of the Gaussians actually generated the pattern. The parameters of our statistical model are then of two types: those α affecting the probability distributions of the hidden variables \mathbf{h} , and those β affecting the rest of parameters of the model. Therefore, $\Theta = \{\alpha, \beta\}$. For instance, if the statistical model is a mixture of Gaussians, α contains the prior probabilities of the different Gaussians, and β is composed by the averages and covariance matrices. Finally, we assume that the penalization term can be written as:

$$\ln \tilde{P}(\Theta_{\text{Te}}|\Theta_{\text{Tr}}) = \ln \tilde{P}(\alpha_{\text{Te}}|\alpha_{\text{Tr}}) + \ln \tilde{P}(\beta_{\text{Te}}|\beta_{\text{Tr}})$$

We are now in a position to develop the semi-supervised extension of EM. Following the same scheme of reasoning as in exercise 44 of chapter 3 in (Duda, Hart & Stork, 2001) we arrive at the following algorithm:

- Initialize $\alpha'_{\text{Te}} \leftarrow \alpha_{\text{Tr}}$ and $\beta'_{\text{Te}} \leftarrow \beta_{\text{Tr}}$
- (E step): Compute for all \mathbf{h} and \mathbf{x}_i :

$$\tilde{P}(\mathbf{h}|\mathbf{x}_i, \alpha'_{\text{Te}}, \beta'_{\text{Te}}) = \frac{\tilde{P}(\mathbf{x}_i|\mathbf{h}, \beta'_{\text{Te}}) \cdot \tilde{P}(\mathbf{h}|\alpha'_{\text{Te}})}{\sum_{\mathbf{h}'} \tilde{P}(\mathbf{x}_i|\mathbf{h}', \beta'_{\text{Te}}) \cdot \tilde{P}(\mathbf{h}'|\alpha'_{\text{Te}})}$$

- (M step):
Calculate the α^*_{Te} that maximizes the following quantity (fixing α'_{Te} and β'_{Te}):

$$\ln \tilde{P}(\alpha^*_{\text{Te}}|\alpha_{\text{Tr}}) + \sum_{\mathbf{h}, \mathbf{x}_i} \tilde{P}(\mathbf{h}|\mathbf{x}_i, \alpha'_{\text{Te}}, \beta'_{\text{Te}}) \cdot \ln \tilde{P}(\mathbf{h}|\alpha^*_{\text{Te}})$$

Calculate the β^*_{Te} that maximizes the following quantity (fixing α'_{Te} and β'_{Te}):

$$\ln \tilde{P}(\beta^*_{\text{Te}}|\beta_{\text{Tr}}) + \sum_{\mathbf{h}, \mathbf{x}_i} \tilde{P}(\mathbf{h}|\mathbf{x}_i, \alpha'_{\text{Te}}, \beta'_{\text{Te}}) \cdot \ln \tilde{P}(\mathbf{x}_i|\mathbf{h}, \beta^*_{\text{Te}})$$

- Update the parameters: $\alpha'_{\text{Te}} \leftarrow \alpha^*_{\text{Te}}$ and $\beta'_{\text{Te}} \leftarrow \beta^*_{\text{Te}}$
- Go to step 2 until convergence of L'

In this derivation it is also guaranteed that L' does not decrease at each step, so our algorithm will find at least a local optimum of L' . On the other hand, the penalization term will ensure the stability of the algorithm (small changes in test data lead to small changes in the re-estimation), and will allow to associate the correct class to the different clusters. Our algorithm contains as a special case the standard EM algorithm

when the distribution $\tilde{P}(\Theta_{Te} | \Theta_{Tr})$ is not considered or is assumed to be homogeneous.

In the examples we will show in this chapter we use a simple case of this algorithm where the statistical model consists in one Gaussian per class, and only the averages of the Gaussians are re-estimated. The penalization term $\ln \tilde{P}(\Theta_{Te} | \Theta_{Tr})$ used in these examples is proportional to the Mahalanobis distance (Duda, Hart & Stork, 2001) between the averages estimated in training and those re-estimated in test (we will refer to the proportional factor as γ). Then we arrive at the following simplified algorithm:

1. Initialize $\mu'_{1, Te} \leftarrow \mu_{1, Tr}$ and $\mu'_{2, Te} \leftarrow \mu_{2, Tr}$
2. (E step): Compute for $c=1,2$ and all \mathbf{x}_i in the test dataset:

$$\tilde{P}(c | \mathbf{x}_i) = \frac{\tilde{P}(c) \cdot \tilde{p}(\mathbf{x}_i | \mu'_{c, Te}, \mathbf{M}_c)}{\tilde{P}(1) \cdot \tilde{p}(\mathbf{x}_i | \mu'_{1, Te}, \mathbf{M}_1) + \tilde{P}(2) \cdot \tilde{p}(\mathbf{x}_i | \mu'_{2, Te}, \mathbf{M}_2)}$$

3. (M step):

$$\mu'_{c, Te} \leftarrow \frac{\gamma \cdot (\mu_{c, Tr} + \mathbf{d}) + \frac{1}{N_{Te}} \sum_{\mathbf{x}_i} \tilde{P}(c | \mathbf{x}_i) \cdot \mathbf{x}_i}{\gamma + \frac{1}{N_{Te}} \sum_{\mathbf{x}_i} \tilde{P}(c | \mathbf{x}_i)}$$

and go to step 2 until convergence of L' .

where $c \in \{1, 2\}$ is the class of the pattern; $\tilde{P}(c)$ is the prior probability of class c estimated in the training set; $\mu_{c, Tr}$ and $\mu_{c, Te}$ are the averages of the patterns of class c in training and test sets respectively; \mathbf{M}_c is the covariance matrix of class c estimated in the training set; $\tilde{p}(\mathbf{x} | \mu, \mathbf{M})$ is the probability density function of \mathbf{x} given that it has been generated by a Gaussian process of average μ and covariance matrix \mathbf{M} ; \mathbf{d} is the subtraction of the global average of the attributes in test to the global average of the attributes in training; and N_{Te} is the number of patterns in test.

Application to a Synthetic Problem

First we will illustrate our algorithm using a simple synthetic problem with two classes (figure 2). In training, class “grey” was generated from a Gaussian distribution with average $[1.0 ; 1.0]$ and covariance matrix $[0.5, 0.0$

; $0.0, 0.5]$; class “black” was generated from a Gaussian distribution with average $[1.0 ; 1.5]$ and covariance matrix $[0.5, 0.4 ; 0.4, 0.5]$. The statistical structure of the test set is different than in training due to a shift of class “black” (figure 2a and 2b), now with average $[2.0 ; 1.0]$. The minimum Bayes’ errors of training and test sets are 27.7% and 18.8% respectively.

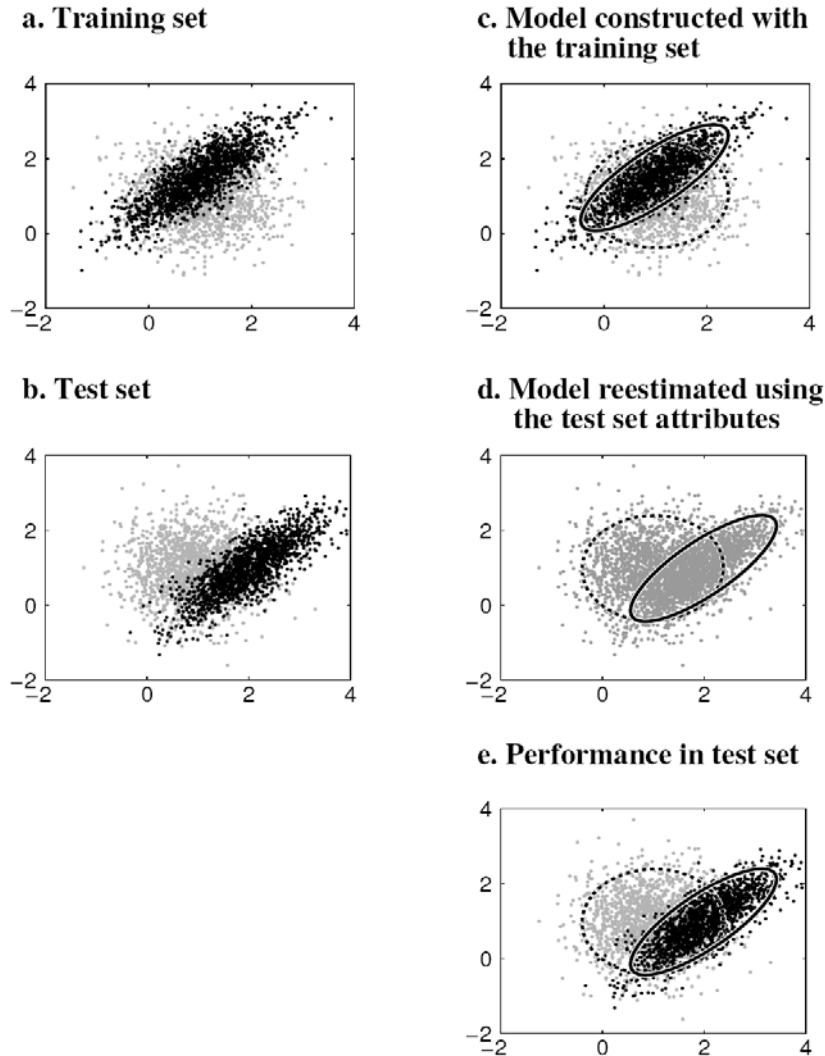

First we construct a statistical model of the training set consisting in one Gaussian for each class (figure 2c). This statistical model is then used to construct a classifier based on Linear Discriminant Analysis (LDA). The error of this classifier in training is 34.1%. When applied to test set, the error of this classifier increases to 66.0%. Our algorithm was then used to re-estimate the statistical model constructed in training using the unlabelled test set patterns (figure 2d). We can observe that our algorithm finds the appropriate statistical model for the test set (figure 2e). In fact, when we recalculated the LDA classifier using the re-estimated statistical model, the error in test decreased to 20.5%.

Application to Heart Disease Diagnosis when the Training and Test Hospitals are Different

We tested our algorithm using the Heart disease database from the UCI machine learning repository (Asuncion & Newman, 2007). The goal is to predict whether a patient has a heart disease or not, given some personal data (age, sex, smoking habits, etc.) and the results of several medical examinations such as blood pressure and electro cardiograms. The Heart disease database is in fact the union of four datasets, each one obtained at a different hospital. One would expect that the statistical structure of the problem is different in different hospitals since the patients live in different cities (and thus the environmental factors can be different), the measurement devices are not exactly the same, etc. Thus we expect that our algorithm will improve the classification performance of a model constructed in a different hospital.

We have checked this hypothesis using the data from the Cleveland Clinic Foundation as training, and the data from the Hungarian Institute of Cardiology as test. In both cases we removed the attributes in columns 12 and 13 since they are frequently missing in the Hungarian dataset, and performed a normalization in each set so the attributes have zero mean and unit variance. The result is 297 examples from the Cleveland Clinic (149

Figure 2. Re-estimation of the statistical model of the problem in a synthetic example. The two different classes are shown as two different clouds (grey and black). a, b: the statistical structure of the problem in training is different than in test. c: statistical model constructed from the training set (dashed: model for class “grey”; solid: model for class “black”). d: recalculation of the statistical model using the unlabelled test set (note that we have drawn all patterns in grey since the re-estimation algorithm does not have access to the classes of the test patterns). e: Re-estimated statistical model superposed with the labelled test set (dashed: model for class “grey”; solid: model for class “black”).

of class 1, 148 of class 2), and 294 from the Hungarian Institute of Cardiology (188 of class 1, 106 of class 2). First, we use PCA to reduce the dimensionality of the problem in the training set. Therefore the statistical model of our problem now consists of the average and covariance matrix of each class in the principal axes. Then, a simple classifier that assigns to pattern \mathbf{x} the class with nearest center is considered. The number of

principal components is automatically selected on the basis of the performance of the classifier in a random subset of the training dataset which was reserved for this task. Once the statistical model of the training set is constructed, we evaluated the performance of the classifier in the test set obtaining an error rate of 18.7%.

In a second step we used our algorithm for re-estimating the statistical model using $\gamma=0.01$, and then

classified the test patterns using the same procedure as before, that is, assigning to each test pattern the class with nearest center. The error was reduced in this case to 15.3 %. If we repeat the same strategy using a more elaborated classifier such as one based on Linear Discriminant Analysis, we observe a reduction in the error from 17.0% to 13.9% after using our algorithm.

FUTURE TRENDS

In the examples we have presented here we have used a simplified version of our algorithm that assumes a statistical model consisting of one Gaussian for each class, and that only the averages need to be re-estimated with test. However, our semi-supervised extension of EM is a general algorithm that is applicable with arbitrary parametric statistical models (e.g. mixtures of an arbitrary number of non Gaussian models), and allows to re-estimate any parameter of the model. Future work will include the study of the performance and robustness of different types of statistical models in practical problems. On the other hand, since our approach is based on an extension of the extensively studied standard EM algorithm, we expect that analytical results such as generalization error bounds can be derived, making the algorithm attractive also from a theoretical perspective.

CONCLUSION

We have presented a new learning strategy for classification problems where the statistical structure of training and test sets are different. In this kind of problems, the performance of traditional machine learning algorithms can be severely degraded. Different techniques have been proposed to cope with different aspects of the problem, such as strategies for addressing the sample selection bias (Heckman, 1979; Salganicoff, 1997; Shimodaira, 2000; Zadrozny, 2004; Sugiyama, Krauledat & Müller, 2007), strategies for addressing the concept drift (Black & Hickey, 1999; Wang, Fan, Yu & Han, 2003; Widmer & Kubat, 1996) and transductive learning (Vapnik, 1998; Wu, Bennett, Cristianini & Shawe-Taylor, 1999).

The learning strategy we have presented allows to address all these different aspects, so that it can be used in problems where concept drift, sampling biases, or any

other phenomena exist that cause the statistical structure of training and test sets to be different. Moreover, our algorithm constructs an explicit statistical model of the new structure in the test dataset, which is of great value for understanding the dynamics of the problem and exploiting this knowledge in practical applications. To achieve this we have extended the EM algorithm obtaining a semi-supervised version that allows to re-estimate the statistical model constructed in training using the attribute distribution of the unlabelled test set patterns.

KEY TERMS

Attribute: Each of the components that constitute an input pattern.

Classifier: Function that associates a class c to each input pattern \mathbf{x} of interest. A classifier can be directly constructed from a set of pattern examples with their respective classes, or indirectly from a statistical model $\tilde{P}(\mathbf{x}, c)$.

EM (Expectation-Maximization Algorithm): standard iterative algorithm for estimating the parameters Θ of a parametric statistical model. EM finds the specific parameter values that maximize the likelihood of the observed data D given the statistical model, $\tilde{P}(D|\Theta)$. The algorithm alternates between the Expectation step and the Maximization step, finishing when $\tilde{P}(D|\Theta)$ meets some convergence criterion.

Missing Value: Special value of an attribute that denotes that it is not known or can not be measured.

Semi-Supervised Learning: Machine learning technique that uses both labelled and unlabelled data for constructing the model.

Statistical Model: Mathematical function that models the statistical structure of the problem. For classification problems, the statistical model is $\tilde{P}(\mathbf{x}, c)$ or equivalently $\{ \tilde{P}(\mathbf{x}|c), \tilde{P}(c) \}$ since $\tilde{P}(\mathbf{x}, c) = \tilde{P}(\mathbf{x}|c) \cdot \tilde{P}(c)$.

Supervised Learning: Type of learning where the objective is to learn a function that associates a desired output ('label') to each input pattern. Supervised learning techniques require a training dataset of examples with their respective desired outputs. Supervised learning is traditionally divided into regression (the desired output is a continuous variable) and classification (the desired output is a class label).

Training/Test Sets: In the context of this chapter, the training set is composed by all labelled examples that are provided for constructing a classifier. The test set is composed by the new unlabelled patterns whose classes should be predicted by the classifier.

Cluster Analysis of Gene Expression Data

INTRODUCTION

Important insights into gene function can be gained by gene expression analysis. For example, some genes are turned on (expressed) or turned off (repressed) when there is a change in external conditions or stimuli. The expression of one gene is often regulated by the expression of other genes. A detail analysis of gene expression information will provide an understanding about the inter-networking of different genes and their functional roles.

DNA microarray technology allows massively parallel, high throughput genome-wide profiling of gene expression in a single hybridization experiment [Lockhart & Winzeler, 2000]. It has been widely used in numerous studies over a broad range of biological disciplines, such as cancer classification (Armstrong et al., 2002), identification of genes relevant to a certain diagnosis or therapy (Muro et al., 2003), investigation of the mechanism of drug action and cancer prognosis (Kim et al., 2000; Duggan et al., 1999). Due to the large number of genes involved in microarray experiment study and the complexity of biological networks, clustering is an important exploratory technique for gene expression data analysis. In this article, we present a succinct review of some of our work in cluster analysis of gene expression data.

BACKGROUND

Cluster analysis is a fundamental technique in exploratory data analysis (Jain & Dubes, 1988). It aims at finding groups in a given data set such that objects in the same group are similar to each other while objects in different groups are dissimilar. It aids in the discovery of

gene function because genes with similar gene expression profiles can be an indicator that they participate in related cellular processes. Clustering of genes may suggest possible roles for genes with unknown functions based on the known functions of some other genes in the same cluster. Clustering of gene expression data has been applied to, for example, the study of temporal expression of yeast genes in sporulation (Chu et al., 1998), the identification of gene regulatory networks (Chen, Filkov, & Skiena, 1999), and the study of cancer (Tamayo et al., 1999).

Many clustering algorithms have been applied to the analysis of gene expression data (Sharan, Elkon, & Shamir, 2002). They can be broadly classified as either hierarchical or partition-based depending on how they group the data. Hierarchical clustering is further subdivided into agglomerative methods and divisive methods. The former proceed by successive merging of the N objects into larger groups, whereas the latter divide a larger group successively into finer groupings. Agglomerative techniques are more common in hierarchical clustering.

Hierarchical clustering is among the first clustering technique being applied to gene expression data (Eisen et al., 1998). In hierarchical clustering, each of the gene expression profile is considered as a cluster initially. Then, pairs of clusters with the smallest distance between them, are merged together to form a single cluster. This process is repeated until there is only one cluster left. The hierarchical clustering algorithm arranges the gene expression data into a hierarchical tree structure known as a dendrogram, which allows easy visualization and interpretation of results. However, the hierarchical tree cannot indicate the optimal number of clusters in the data. The user has to interpret the tree topologies and identify branch

points that segregate clusters of biological relevance. In addition, once a data is assigned to a node in the tree, it cannot be reassigned to a different node even though it is later found to be closer to that node.

In partition-based clustering algorithms, such as K-means clustering (Jain & Dubes, 1988), the number of clusters is arbitrarily fixed by the users at start. Setting the correct number of clusters can be a difficult problem and many heuristics are used. The basic idea of K-means clustering is to partition the data into a predefined number of clusters such that the variability of the data within each cluster is minimized. Clustering is achieved by first generating K random cluster centroids, then alternately updating the cluster assignment of each data vector and the cluster centroids. The Euclidean distance is usually employed in K-means clustering to measure the closeness of a data vector to the cluster centroids. However, such distance metric inevitably imposes an ellipsoidal structure on the resulting clusters. Hence, data that do not conform to this structure are poorly clustered by the K-means algorithm.

Other approach to clustering includes model-based approach. In contrast to model-free partition-based algorithms, model-based clustering uses certain dis-

tribution models for clusters and attempts to optimize the fit between the data and the model. Each cluster is represented by a parametric distribution, like a Gaussian, and the entire data set is modeled by a mixture of these distributions. The most widely used clustering method of this kind is the one based on a mixture of Gaussians (McLachlan & Basford, 1988; Yeung et al., 2001).

CLUSTERING OF GENE EXPRESSION DATA

Binary Hierarchical Clustering (BHC): In Szeto et al. (2003), we proposed the BHC algorithm for clustering gene expression data based on the hierarchical binary subdivision framework of Clausi (2002). Consider the dataset with three distinct classes as shown in Fig. 1. The algorithm starts by assuming that the data consists of one class. The first application of binary subdivision generates two clusters A and BC. As the projection of class A and class BC have a large enough Fisher criterion on the A-BC discriminant line, the algorithm splits the original dataset into two clusters. Then, the binary subdivision is applied onto each of the two clusters. The

Figure 1. The binary subdivision framework. (a) Original data treated as one class, (b) Partition into two clusters, A and BC. (c) Cluster A cannot be split further, but cluster BC is split into two clusters, B and C. (d) Both cluster B and C cannot be split any more, and we have three clusters A, B, and C. (Figure adopted from Clausi (2002))

BC cluster is separated into B and C clusters because its Fisher criterion is large. However, the Fisher criterion of cluster A is too small to allow further division, so it remains as a single cluster. Such subdivision process is repeated until all clusters have Fisher criterion too low for further splitting and the process stops.

The BHC algorithm proceeds in two steps: (1) binary partition using a mixed FCM-HC algorithm to partition the data into two classes, (2) Fisher discriminant analysis on the two classes, where if the Fisher criterion exceeds a set threshold, we accept the partition; otherwise do not subdivide the data any further.

A novel aspect of the BHC algorithm is the use of the FCM-HC algorithm to partition the data. The idea is illustrated in Fig.2a-2c. In Fig.2a, there are three clusters. The desirable two-class partition would be for the two closer clusters to be classified as one partition and the remaining cluster as the second partition. However, a K-means partitioning of the data would favor the split of the middle cluster into two classes. With this wrong partition, subsequent Fisher discriminant analysis would conclude that the splitting is not valid and the data should be considered as just one class. To overcome this problem, we first over-cluster the data into several clusters by the Fuzzy C-means (FCM) algorithm. Then, the clusters are merged together by the average linkage hierarchical clustering (HC) algorithm until only two classes are left. In Fig.2a, the data is over-clustered into six clusters by the FCM algorithm. A hierarchical tree constructed from the six clusters using the average linkage clustering algorithm is constructed as in Fig.2b. Using the cutoff as shown in

Fig.2b, a final partitioning of the data into two classes is shown in Fig.2c. We can see that A, B are merged into one class, and C, E, F, D are merged into the second class. FCM-HC also allows non-ellipsoidal clusters to be partitioned correctly. Fig.2d shows a dataset containing two non-ellipsoidal clusters that is over-clustered into six clusters. After merging, we obtain the correct two-class partitions as shown in Fig.2e.

The BHC algorithm makes no assumption about the class distributions and the number of clusters is determined automatically. The only parameter required is the Fisher threshold. The binary hierarchical framework naturally leads to a tree structure representation where similar clusters are placed adjacent to each other in the tree. Near the root of the tree, only gross structures in the data are shown, whereas near the end branches, fine details in the data can be visualized. Figure 3 shows the BHC clustering results on Spellman's yeast dataset (<http://celcycle-www.stanford.edu>). The dataset contains expression profiles for 6178 genes under different experimental conditions, i.e., cdc15, and cdc28, alpha factor and elutriation experiments.

Self-Splitting and Merging Competitive Learning (SSMCL) Clustering: In Wu, Liew, & Yan (2004), we proposed a new clustering framework based on the one-prototype-take-one-cluster (OPTOC) learning paradigm (Zhang & Liu, 2002) for clustering gene expression data. The new algorithm is able to identify natural clusters in the data as well as provide a reliable estimate of the number of distinct clusters in the data. In conventional clustering, if the number of

Figure 2. Partition of the data into two classes, where the original data is clustered into six clusters (a) with the resulting hierarchical tree (b), and finally the two-class partition after merging (c). For two non-ellipsoidal clusters, FCM-HC over-clusters them into 6 classes (d), and the resulting two-class partition after merging (e).

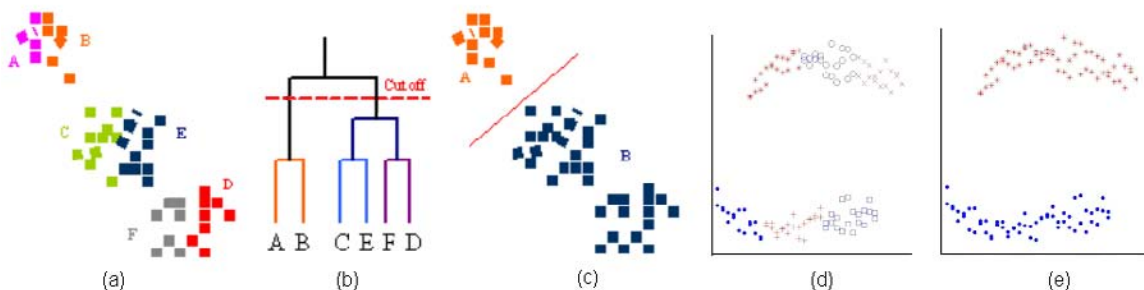

Figure 3. BHC clustering of (a) alpha factor experiment dataset, (b) *cdc15* experiment dataset, (c) elutriation experiment dataset, and (d) *cdc28* experiment dataset.

prototypes is less than that of the natural clusters in the data, then at least one prototype will win patterns from more than two clusters. In contrast, the OPTOC idea allows one prototype to characterize only one natural cluster in the data, regardless of the actual number of clusters in the data. This is achieved by constructing a dynamic neighborhood such that patterns inside the neighborhood contribute more to its learning than those outside. Eventually, the prototype settles at the center of a natural cluster, while ignoring competitions from other clusters as shown in Fig. 4b.

The SSMCL algorithm starts with a single cluster. If the actual number of clusters in the data is more than one, additional prototypes are generated to search for the remaining clusters. Let C_i denotes the center of all the patterns that P_i wins according to the minimum

distance rule. The distortion $|P_i - C_i|$ measures the discrepancy between the prototype P_i found by OPTOC learning and the actual cluster structure in the data. For example, in Fig. 4b, C_1 would be located at the center of the three clusters $S1$, $S2$ and $S3$ (since there is only one prototype, it wins all input patterns), while P_1 eventually settled at the center of $S3$. After the prototypes have all settled down, a large $|P_i - C_i|$ indicates the presence of other natural clusters in the data. A new prototype would be generated from the prototype with the largest distortion when this distortion exceeds a certain threshold ε .

Ideally, with a suitable threshold, the algorithm will find all natural clusters in the data. Unfortunately, the complex structure exhibited by gene expression data makes setting an appropriate threshold difficult. Instead,

Figure 4. Two learning methods: conventional versus OPTOC. (a) One prototype takes the arithmetic center of three clusters (conventional learning). (b) One prototype takes one cluster (OPTOC learning) and ignores the other two clusters.

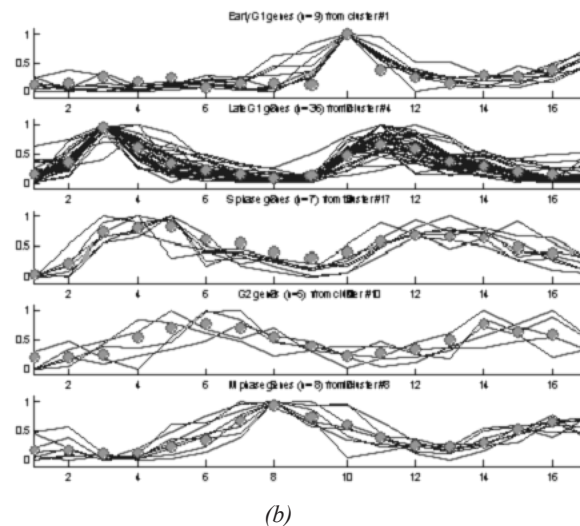

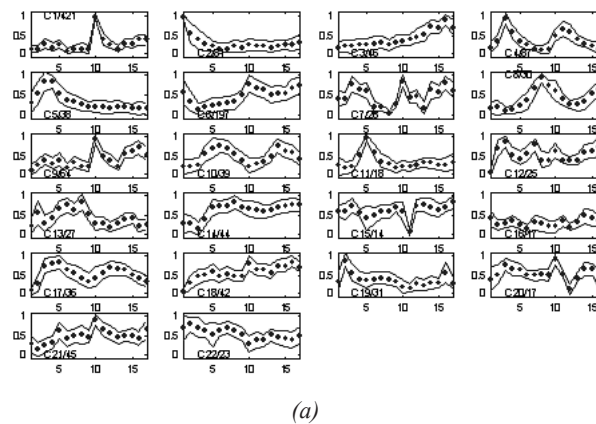

Figure 5. (a) The 22 distinct clusters found by SSMCL for the yeast cell cycle data. (b) Five patterns that correspond to the five cell cycle phases. The genes presented here are only those that belong to these clusters and are biologically characterized to a specific cell cycle phase.

we proposed an over-clustering and merging strategy. The over-clustering step minimizes the chance of missing any natural clusters in the data, while the merging step ensures that the final clusters are all visually distinct from each other. In over-clustering, a natural cluster might be split into more than one cluster. However, no one cluster may contain data from several natural clusters, since the OPTOC paradigm discourages a cluster from winning data from more than one natural cluster. The clusters that are visually similar would be merged during the merging step. Together with the OPTOC framework, the over-clustering and merging framework allows a systematic estimation of the correct number of natural clusters in the data.

Fig.5a shows the SSMCL clustering result for the yeast cell cycle expression data (<http://genomics.stanford.edu>). We observe that the 22 clusters found have no apparent visual similarity. We checked the 22 clusters with the study of Cho et al. (1998), where 416 genes have been interpreted biologically. Those gene expression profiles include five fundamental patterns that correspond to five cell cycles phases: early G1, late G1, S, G2, and M phase. Fig.5b shows the five clusters that contain most of the genes belonging to these five different patterns. It is obvious that these five clusters correspond to the five cell cycle phases.

FUTURE TRENDS

Microarray data is usually represented as a matrix with rows and columns correspond to genes and conditions respectively. Conventional clustering algorithms can be applied to either rows or columns but not simultaneously. However, an interesting cellular process is often active only in a subset of conditions, or a single gene may participate in multiple pathways that may not be co-active under all conditions. Biclustering methods allow the clustering of rows and columns simultaneously. Existing biclustering algorithms often iteratively search for the best possible sub-grouping of the data by permuting rows and columns of the data matrix such that an appropriate merit function is improved (Madeira & Oliveira, 2004). When different bicluster patterns co-exist in the data, no single merit function can adequately cater for all possible patterns. Although recent approach such as geometric biclustering (Gan, Liew & Yan, 2008) has shown great potential, much work is still needed here. It is also important to de-

velop visualizing tools for the high dimensional gene expression clusters. The parallel coordinate plot is a well-known visualization technique for high dimension data and we are currently investigating it for bicluster visualization (Cheng et al., 2007).

CONCLUSION

Cluster analysis is an important exploratory tool for gene expression data analysis. This article describes two recently proposed clustering algorithms for gene expression data. In the BHC algorithm, the data are successively partitioned into two classes using the Fisher criterion. The binary partitioning leads to a tree structure representation which facilitates easy visualization. In the SSMCL algorithm, the OPTOC learning framework allows the detection of natural clusters. The subsequent over-clustering and merging step then allows a systematic estimation of the correct number of clusters in the data. Finally, we discuss some possible avenues of future research in this area. The problem of biclustering of gene expression data is a particularly interesting topic that warrants further investigation.

KEY TERMS

BHC Clustering: A clustering algorithm based on the hierarchical binary subdivision framework. The algorithm proceeds by partitioning a cluster into two classes, and then check for the validity of the partition by Fisher discriminant analysis. The algorithm terminates when no further valid subdivision is possible.

Biclustering: Also called two-way clustering or co-clustering. In biclustering, not only the objects but

also the features of the objects are clustered. If the data is represented in a data matrix, the rows and columns are clustered simultaneously.

Cluster Analysis: An exploratory data analysis technique that aims at finding groups in a data such that objects in the same group are similar to each other while objects in different groups are dissimilar.

DNA Microarray technology: A technology that allows massively parallel, high throughput genome-wide profiling of gene expression in a single hybridization experiment. The method is based on the complementary hybridization of DNA sequence.

Gene Expression: Gene expression is the process by which a gene's DNA sequence is converted into functional proteins. Some genes are turned on (expressed) or turned off (repressed) when there is a change in external conditions or stimuli.

Hierarchical Clustering: A clustering method that finds successive clusters using previously established clusters. Hierarchical algorithms can be agglomerative (bottom-up) or divisive (top-down). Agglomerative algorithms begin with each element as a separate cluster

and merge them into successively larger clusters. Divisive algorithms begin with the whole set and proceed to divide it into successively smaller clusters.

K-Means Clustering: K-means clustering is the most well-known partition-based clustering algorithm. The algorithm starts by choosing k initial centroids, usually at random. Then the algorithm alternates between updating the cluster assignment of each data point by associating with the closest centroid and updating the centroids based on the new clusters until convergence.

SSMCL Clustering: A partition-based clustering algorithm that is based on the one-prototype-take-one-cluster (OPTOC) learning paradigm. OPTOC learning is achieved by constructing a dynamic neighborhood that favors patterns inside the neighborhood. Eventually, the prototype settles at the center of a natural cluster, while ignoring competitions from other clusters. Together with the over-clustering and merging process, SSMCL is able to find all natural clusters in the data.

Clustering Algorithm for Arbitrary Data Sets

Hai-Dong Meng

Inner Mongolia University of Science and Technology, China

INTRODUCTION

Clustering analysis is an intrinsic component of numerous applications, including pattern recognition, life sciences, image processing, web data analysis, earth sciences, and climate research. As an example, consider the biology domain. In any living cell that undergoes a biological process, different subsets of its genes are expressed in different stages of the process. To facilitate a deeper understanding of these processes, a clustering algorithm was developed (Bendor, Shamir, & Yakhini, 1999) that enabled detailed analysis of gene expression data. Recent advances in proteomics technologies, such as two-hybrid, phage display and mass spectrometry, have enabled the creation of detailed maps of biomolecular interaction networks. To further understanding in this area, a clustering mechanism that detects densely connected regions in large protein-protein interaction networks that may represent molecular complexes was constructed (Bader & Hogue, 2003). In the interpretation of remote sensing images, clustering algorithms (Sander, Ester, Kriegel, & Xu, 1998) have been employed to recognize and understand the content of such images. In the management of web directories, document annotation is an important task. Given a predefined taxonomy, the objective is to identify a category related to the content of an unclassified document. Self-Organizing Maps have been harnessed to influence the learning process with knowledge encoded within a taxonomy (Adami, Avesani, & Sona, 2005). Earth scientists are interested in discovering areas of the ocean that have a demonstrable effect on climatic events on land, and the SNN clustering technique (Ertöz, Steinbach, & Kumar, 2002) is one example of a technique that has been adopted in this domain. Also, scientists have developed climate indices, which are time series that summarize the behavior of selected regions of the Earth's oceans and atmosphere. Clustering techniques have proved

crucial in the production of climate indices (Steinbach, Tan, Kumar, Klooster, & Potter, 2003).

In many application domains, clusters of data are of arbitrary shape, size and density, and the number of clusters is unknown. In such scenarios, traditional clustering algorithms, including partitioning methods, hierarchical methods, density-based methods and grid-based methods, cannot identify clusters efficiently or accurately. Obviously, this is a critical limitation. In the following sections, a number of clustering methods are presented and discussed, after which the design of an algorithm based on Density and Density-reachable (CADD) is presented. CADD seeks to remedy some of the deficiencies of classical clustering approaches by robustly clustering data that is of arbitrary shape, size, and density in an effective and efficient manner.

BACKGROUND

Clustering aims to identify groups of objects (clusters) that satisfy some specific criteria, or share some common attribute. Clustering is a rich and diverse domain, and many concepts have been developed as the understanding of clustering develops and matures (Tan, Steinbach, & Kumar, 2006). As an example, consider spatial distribution. A typology of clusters based on this includes: Well-separated clusters, Center-based clusters, Contiguity-based clusters, and Density-based clusters. Given the diversity of domains in which clustering can be applied, and the diverse characteristic and requirements of each, it is not surprising that numerous clustering algorithms have been developed. The interested reader is referred to the academic literature (Qiu, Zhang, & Shen, 2005), (Ertöz, Steinbach, & Kumar, 2003), (Zhao, Song, Xie, & Song, 2003), (Ayad & Kamel, 2003), (Karypis, Han, & Kumar, 1999) for further information.

Though the range of clustering algorithms that have been developed is broad, it is possible to classify them according to the broad approach or method adopted by each:

- A partitioning method creates an initial set of k partitions, where the parameter k is the number of partitions to be constructed. Then it uses an iterative relocation technique that attempts to improve the partitioning by moving objects from one group to another. Typical partitioning methods include K-means, K-medoids, CLARANS, and their derivatives.
- A hierarchical method creates a hierarchical decomposition of the given set of data objects. The method can be classified as being either agglomerative (bottom-up) or divisive (top-down), based on how the hierarchical decomposition is formed. To compensate for the rigidity of the merge or split, the quality of hierarchical agglomeration can be improved by analyzing object linkages at each hierarchical partition - an approach adopted by the CURE and Chameleon algorithms, or by integrating other clustering techniques such as iterative relocation - an approach adopted by BIRCH.
- A density-based method clusters objects based on the concept of density. It either grows the cluster according to the density of the neighborhood objects (an approach adopted by DBSCAN), or according to some density function (such that used by DENCLUE).
- A grid-based method first quantizes the object space into a finite number of cells thus forming a grid structure, and then performs clustering on the grid structure. STING is a typical example of a grid-based method based on statistical information stored in grid cells. CLIQUE and Wave Cluster are examples of two clustering algorithms that are both grid-based and density-based.
- A model-based method hypothesizes a model for each of the clusters and finds the best fit of the data to that model. Typical model-based methods involve statistical approaches (such as COBWER, CLASSIT, and AutoClass).

In essence, practically all clustering algorithms attempt to cluster data by trying to optimize some objective function.

DEVELOPMENT OF A CLUSTERING ALGORITHM

Before the development of a clustering algorithm can be considered, it is necessary to consider some problems intrinsic to clustering. In data mining, efforts have focused on finding methods for efficient and effective cluster analysis in large databases. Active themes of research focus on the effectiveness of methods for clustering complex shapes and types of data, high-dimensional clustering techniques, scalability of clustering methods, and methods for clustering mixed numerical and categorical data in large databases. When clustering algorithms are analyzed, it is obvious that there are some intrinsic weaknesses that affect their applicability:

- Reliability to parameter selection - for partitioning methods and hierarchical methods, it is necessary to input parameters both for the number of clusters and the initial centroids of the clusters. This is difficult for unsupervised data mining when there is lack of relevant domain knowledge (Song & Meng, 2005 July), (Song & Meng, 2005 June). At the same time, different random initializations for number of clusters and centroids of clusters produce diverse clustering results, indicating a lack of stability on the part of the clustering method.
- Sensitivity to noise and outliers - noise and outliers can unduly influence the clusters derived by partitioning methods, hierarchical methods, grid-based methods, and model-based methods; however partitioning methods and hierarchical methods are particularly susceptible.
- Selectivity to cluster shapes - partitioning methods, hierarchical methods, and grid-based methods are not suitable for all types of data distribution, and cannot handle non-globular clusters of different shapes, sizes and densities.
- Ability to detect outliers - density-based methods are relatively resistant to noise and can handle clusters of arbitrary shapes and sizes, but can not detect outliers effectively.

Experimental Analysis of Traditional Clustering Algorithms

In order to visually illustrate the clustering results, two-dimensional data sets as experimental data are used. However, it should be noted that the analysis results are also suitable for higher dimensional data.

Partitioning Method

K-means, a partitioning method, is one of the most commonly used clustering algorithms, but it does not perform well on data with outliers or with clusters of different sizes or non-globular shapes. This clustering method is the most suitable for capturing clusters with globular shapes, but this approach is very sensitive to noise and cannot handle clusters of varying density.

Hierarchical Method

Hierarchical clustering techniques are a second important category of clustering methods, but the most commonly used methods are agglomerative hierarchical algorithms. Agglomerative hierarchical algorithms are expensive in terms of their computational and storage requirements. The space and time complexity of such algorithms severely restricts the size of the data sets that can be used. Agglomerative hierarchical algorithms identify globular clusters but cannot find non-globular clusters, and also cannot identify any outliers or noise points. CURE relies on an agglomerative hierarchical scheme to perform the actual clustering. The distance between two clusters is defined as the minimum distance between any two of their representative points (after the representative points are shrunk toward their

respective centres). During this hierarchical clustering process, CURE eliminates outliers by eliminating small, slowly growing clusters. Although the concept of representative points does allow CURE to find clusters of different sizes and shapes in some data sets, CURE is still biased towards finding globular clusters, as it still incorporates the notion of a cluster centre.

Density-Based Methods

Density-based clustering locates regions of high density that are separated from one another by regions of low density. DBSCAN is a typical and effective density-based clustering algorithm which can find different types of clusters, identify outliers and noise, but it can not handle clusters of varying density. DBSCAN can have difficulty with density if the density of clusters and noise varies widely. Consider Figure 1, which illustrates three clusters embedded in noises of unequal densities. The noise around the clusters A and B has the same density as cluster C. If the Eps threshold is high enough such that DBSCAN finds A and B as separate clusters, and the points surrounding them are marked as noise, then C and the points surrounding it will also be marked as noise.

An Algorithm Based on Density and Density-Reachable

Based on the notions of density and density reachable (Meng & Zhang, 2006), (Meng & Song, 2005), a clustering algorithm that can find clusters of arbitrary shapes and sizes, handle clusters and noises of varying density, minimize the reliability of domain knowledge, and identify outliers efficiently, can be designed. A prerequisite to this is the provision of some key definitions:

1. The density of the data points is defined as the sum of the influence functions associated with each point:

$$\text{density}(x_i) = \sum_{j=1}^n e^{-\frac{d(x_i, x_j)^2}{2\sigma^2}}$$

where the Gaussian influence function

$f_{Gauss}(x_i, x_j) = e^{-\frac{d(x_i, x_j)^2}{2\sigma^2}}$ indicates the density influence of each data points on the density of point x_i ; and σ is the density adjustment parameter which

Figure 1. Clusters embedded in noise points of unequal density

is analogous to be the standard deviation, and governs how quickly the influence of a point drops off.

2. Density-reachable distance is used to determine a circular area of data point x , labeled as $\delta = \{x \mid 0 < d(x_i, x_j) \leq R\}$, the data points of which all belong the same cluster. The formula is:

$$R = \frac{\text{mean}(D)}{n^{\text{coef}R}}$$

where $\text{mean}(D)$ is the mean distance between all data points in data set, and $\text{coef}R$ is the adjustment coefficient of the density-reachable distance.

3. Local density attractors are the data points at which the value of the density function is a local maximum.
4. Density-reachable is defined as follows: if there is an object's chain $p_1, p_2, \dots, p_n, p_n = q$, q is a local density attractor, and p_{n-1} is density-reachable from q , then for $p_i \in D, (1 \leq i < n-1)$ and $d(p_i, p_{i+1}) < R$, we define that object $p_i, (1 \leq i < n-1)$ as being density-reachable from q .

Exhibit A.

Algorithm Clustering algorithm based on density and density-reachable (CADD)

Input : Data set, adjustment coefficient of density-reachable distance.

Output : Number of clusters, the members of each cluster, outliers or noise points.

Method :

1 : Compute the densities of each data points and construct original data chain table of clustering objects.

2 : $i \leftarrow 1$

3 : **repeat**

4 : Seek the maximum density attractor $O_{\text{DensityMaxi}}$ in the original data chain table of clustering objects as the first cluster center of C_i .

5 : Assign the objects in the data chain which are density reachable from $O_{\text{DensityMaxi}}$ to cluster C_i , and at the same time delete the clustered objects form original data chain table.

6 : $i \leftarrow i+1$

THE CADD ALGORITHM

See Exhibit A.

Experimental Results

The clustering algorithm was developed using C++. In order to verify the effectiveness of the algorithm, a large number of experiments were carried out with different data sets which contain clusters of different shape, size, and density. The results are now considered.

Clusters of Complex Shapes

The clustering results of clusters of arbitrary shapes and sizes are shown in Figure 2 and Figure 3, the data set being taken from (Karypis et al., 1999).

In contrast to partitioning and hierarchical methods, the clustering algorithm CADD identified the clusters of arbitrary shapes and sizes, and identified the outliers effectively.

Clusters of Varying Density

Density-based methods can perform poorly when clusters have widely differing densities. The clustering algorithm CADD assign each object to a cluster accord-

Figure 2. Clustering result of winded clusters

Figure 3. Clustering result of complex clusters

ing to density-reachable. When managing clusters of varying density, it is important to adjust the distance of density-reachable. This adjustment is carried out by multiplying the original density-reachable distance by the ratio of the density of the first density attractor to the density of the second density attractor, so as to succeed in identifying clusters of varying density. This is because when the density of the local density attractor of a cluster is larger, the distance between objects in the cluster is smaller, and conversely, when the density of the local density attractor of a cluster is smaller, the distance between objects in the cluster is larger.

Figure 4 demonstrates that CADD identifies three clusters C1, C2, and C3 of varying density and which are embedded in outliers or noise points of unequal density. The clustering result reflects the characteristics of data distribution, and is not affected by varying density.

Experimental Analysis of Computational Complexity

After increasing the size of the experimental data set, the run times of DBSCAN and CADD were recorded, as shown in Figure 5. The workstation used to perform the experiment was equipped with 1.6GHz CPU, 512MB

storage, and 80GB hard disk. All objects in the data set possessed 117 attributes.

The basic time complexity of DBSCAN is $O(n \times \text{time to find objects in the } Eps\text{-neighborhood})$, where n is the number of data objects). In the worst case, this complexity is $O(n^2)$. However, in low-dimensional spaces, there are data structures, such as kd-trees, that allow efficient retrieval of all objects within a given distance of a specified point, and the time complexity can be as low as $O(n \log n)$. The space complexity of DBSCAN is $O(n)$. The basic time complexity of CADD is $O(kn)$, where k is the number of clusters. This is because it is only necessary to search the density-reachable objects in the data set once for each cluster, and in the worst case, the time complexity will be $O(n^2)$. The space requirement of CADD is $O(n)$.

FUTURE TRENDS

As many different clustering algorithms have been developed in a variety of domains for different types of applications, details of experimental clustering results

Figure 4. The result of clusters embedded in noises of unequal density

Figure 5. Run times of DBSCAN and CADD

are discussed in many academic texts and research papers. None of these algorithms are suitable for every kind of data, clusters, and applications, and so there is significant scope for developing new clustering algorithms that are more efficient or better suited to a particular type of data, cluster, or application. This trend is likely to continue, as new sources of data are becoming increasingly available. Wireless Sensor Networks (WSNs) are an example of a new technology that can be deployed in a multitude of domains; and such networks will almost invariably give rise to significant quantities of data that will require sophisticated analysis if meaningful interpretations are to be attained.

CONCLUSION

Clustering forms an important component in many applications, and the need for sophisticated, robust clustering algorithms is likely to increase over time. One example of such an algorithm is CADD. Based on the concepts of density and density-reachable, it overcomes some of the intrinsic limitations of traditional clustering mechanisms, and its improved computational efficiency and scalability have been verified experimentally.

KEY TERMS

Cluster Analysis: Cluster analysis groups data objects based only on information found in the data that describes the objects and their relationships.

CADD: A clustering algorithm based on the concepts of Density and Density-reachable.

Centre-Based Clusters: Each object in a centre-based cluster is closer to the centre of the cluster than to the centres of any other clusters.

Contiguity-Based Clusters: Each object in a contiguity-based cluster is closer to some other object in the cluster than to any point in a different cluster.

Density-Based Clusters: Each object in a density-based cluster is closer to some other object within its Eps neighbourhood than to any object not in the cluster, resulting in dense regions of objects being surrounded by regions of lower density.

Eps: Maximum radius of the neighbourhood.

Well-Separated Cluster: A cluster is a set of objects in which each object is significantly closer (or more similar) to every other object in the cluster than to any object not in the cluster.

CNS Tumor Prediction Using Gene Expression Data Part I

INTRODUCTION

Automated diagnosis and prognosis of tumors of the central nervous system (CNS) offer overwhelming challenges because of heterogeneous phenotype and genotype behavior of tumor cells (Yang et al. 2003, Pomeroy et al. 2002). Unambiguous characterization of these tumors is essential for accurate prognosis and therapy. Although the present imaging techniques help to explore the anatomical features of brain tumors, they do not provide an effective means of early detection. Currently, the histological examination of brain tumors is widely used for an accurate diagnosis; however, the tumor classification and grading based on histological appearance does not always guarantee absolute accuracy (Yang et al., 2003, Pomeroy et al., 2002). In many cases, it may not be sufficient to detect the detailed changes in the molecular level using a histological examination (Yang et al. 2003) since such examination may not allow accurate prediction of therapeutic responses or prognosis. If the biopsy sample is too small, the problems are aggravated further.

Toward achieving a more reliable diagnosis and prognosis of brain tumors, gene expression measures from microarrays are the center of attention to many researchers who are working on tumor prediction schemes. Our proposed tumor prediction scheme is discussed in two chapters in this volume. In part I (this chapter), we use an analysis of variance (ANOVA) model for characterizing the Affymetrix gene expression data from CNS tumor samples (Pomeroy et al. 2002) while in part II we discuss the prediction of

tumor classes based on marker genes selected using the techniques developed in this chapter. In this chapter, we estimate the tumor-specific gene expression measures based on the ANOVA model and exploit them to locate the significantly differentially expressed marker genes among different types of tumor samples. We also provide a novel visualization method to validate the marker gene selection process.

BACKGROUND

Numerous statistical methods have evolved that are focused on the problem of finding the marker genes that are differentially expressed among tumor samples (Pomeroy et al., 2002, Islam et al., 2005, Dettling et al., 2002, Boom et al., 2003, Park et al., 2001). For example, Pomeroy et al. (2002) uses student t-test to identify such genes in embryonal CNS tumor samples. Because of the non-normality of gene expression measurements, several investigators have adopted the use of nonparametric methods, such as the Wilcoxon Sum Rank Test (Wilcoxon, 1945) as a robust alternative to the parametric procedures. In this chapter, we investigate a Wilcoxon-type approach and adapt the resulting procedures for locating marker genes.

Typically, statistical procedures for microarray data analysis involve performing gene specific tests. Since the number of genes under consideration is usually large, it is common practice to control the potentially large number of false-positive conclusions and family-wise error rates (the probability of at least one

false positive statement) through the use of P-value adjustments. Pollard et al. (2003) and Van der Laan et al. (2004a, 2004b, 2005c) proposed methods to control family-wise error rates based on the bootstrap resampling technique of Westfall & Young (1993). Benjamini & Hochberg (1995), Efron et al. (2001) and Storey et al. (2002, 2003a, 2003b, 2004) introduced various techniques for controlling the false discovery rate (FDR), which is defined as the expected rate of falsely rejecting the null hypotheses of no differential gene expression. These adjustment techniques have gained prominence in statistical research relating to microarray data analysis. Here, we use FDR control because it is less conservative than family-wise error rates for adjusting the observed P-values for false discovery. In addition, we propose a novel marker gene visualization technique to explore appropriate cutoff selection in the marker gene selection process.

Before performing formal analysis, one should identify the actual gene expression levels associated with different tissue groups and discard or minimize other sources of variations. Such an approach has been proposed by Townsend & Hartl (2002) who use a Bayesian model with both multiplicative and additive small error terms to detect small, but significant differences in gene expressions. As an alternative, an ANOVA model appears to be a natural choice for estimating true gene expression (Kerr et al., 2000, Pavlidis et al., 2001, Wolfinger et al. 2001). In the context of cDNA microarray data, the ANOVA model was first proposed by Kerr et al. (2000).

TUMOR-SPECIFIC GENE EXPRESSION ESTIMATION AND VISUALIZATION TECHNIQUES

To illustrate our procedure, we use the a microarray data set by Pomeroy et al. (2002) of patients with different types of embryonal tumors. The patients include 60 children with medulloblastomas, 10 young adults with malignant gliomas, 5 children with AT/RTs, 5 with renal/extra-renal rhabdoid tumors, and 8 children with supratentorial PNETs. First, we preprocess the data to remove extraneous background noise and array effects. To facilitate our analysis, we divide the dataset into groups as shown in Fig. 1. We rescale the raw expression data obtained from Affymetrix's GeneChip to account for different chip intensities.

Microarray data typically suffer from unwanted sources of variation, such as large-and-small-scale intensity fluctuations within spots, non-additive background, fabrication artifacts, probe coupling and processing procedures, target and array preparation in the hybridization process, background and over-shining effects, and scanner settings (McLachlan & Ambroise, 2005). To model these variations, a number of methods have been reported in the literature (Kerr et al., 2000, Lee et al., 2000, Pavlidis, 2001, Wolfinger et al., 2001, Ranz et al., 2003, Townsend, 2004, Tadesse et al., 2005). An ANOVA model similar to the one used by Kerr et al. (2000) is adopted in our current work and facilitates obtaining the tumor-specific gene expression measures from the preprocessed microarray data. Our two-way ANOVA model is given as:

$$y_{jgk} = \mu + \alpha_g + \beta_j + \gamma_{jg} + \varepsilon_{jgk} \quad (1)$$

Figure 1. Dataset grouping

where, y_{jgk} denotes the log of the gene expression measure for the k th replicate of the g th gene in the j th tumor group ($k = 1, \dots, K_j$; $g = 1, \dots, G$; $j = 1, \dots, J$); μ , α_g , β_j , γ_{jg} refer to the overall effect, the g th gene main effect, the j th tumor-group main effect, and the g th gene - j th tumor group interaction effect, respectively, and ε_{jgk} is a random error with zero mean and constant variance. We assume that these terms are independent; however, we do not make any assumption about their distribution.

This model assumes that background noise and array effects have been eliminated at previous preprocessing steps. This assumption fits well with our preprocessed data. A reason for selecting the model is that it fits well with our goal to build the suitable tumor prototypes for prediction. We believe that tumor prototypes should be built based only on the tumor-specific gene expression measures. In this model, the interaction term γ_{jg} constitutes the actual gene expression of gene g attributed to the tumor type j (McLachlan & Ambroise, 2005). Hence, the value of the contribution to the tumor specific gene expression value by the k th replication of the measurement on gene g in tissue j may be written as given in (McLachlan & Ambroise, 2005), as:

$$\hat{\gamma}_{jgk} = y_{jgk} - \hat{\mu} - \hat{\alpha}_g - \hat{\beta}_j \quad (2)$$

and the tumor specific expression is estimated by Equation (3):

$$\bar{\gamma}_{jg} = \frac{1}{K_j} \sum_{k=1}^{K_j} \hat{\gamma}_{jgk} \quad (3)$$

where, $\hat{\mu} = \bar{y}_{\dots}$, $\hat{\alpha}_g = \bar{y}_{\cdot g} - \bar{y}_{\dots}$ and $\hat{\beta}_j = \bar{y}_{j \cdot} - \bar{y}_{\dots}$ are the least square estimates of the g th gene and j th tumor-group main effects based on replications (Lee et al., 2000, McLachlan & Ambroise, 2005). Here, we regard these estimates as fixed-effects estimates. In a Bayesian analysis, all of the parameters could be treated as random effects. The $\hat{\gamma}_{jgk}$ values are considered in our subsequent steps of the contribution of replicate k to the gene expression of gene g for a patient in the j -th tumor group.

Using several different procedures, such as Shapiro-Wilk's test (Shapiro & Wilk, 1965) and normal probability plots, we observe that the gene expression levels in our dataset are not normally distributed. Hence, we choose a nonparametric test, such as Wilcoxon

(Wilcoxon, 1945), for the two categories problem and the Kruskal-Wallis (NIST, 2007) for the five categories problem in our dataset to identify significantly differentially expressed genes among the tissue sample types. We adjust for multiplicity of the tests involved by controlling the False Discovery Rate (FDR) using q -values as proposed by Storey et al. (2004).

In the selection of differentially expressed genes, a tight cutoff may miss some of the important marker genes, while a generous threshold increases the number of false positives. To address this issue, we use the parallel coordinate plot (Inselberg et al., 1990) of the group-wise average genes expressions. In this plot, the parallel and equally spaced axes represent individual genes. Separate polylines are drawn for each group of tumor samples. The more the average gene expression levels differ between groups, the more space appears among the polylines in the plot. To effectively visualize the differentially expressed genes, we first obtain the average of the tumor-specific gene expression values within any specific tissue sample type $\bar{\gamma}_{jg}$ as specified in Equation (3). We then standardize the average gene expression values $\bar{\gamma}_{jg}$ obtained in Equation (3) as follows:

$$\hat{\gamma}_{jg} = \frac{\bar{\gamma}_{jg}}{S_g} \quad (4)$$

where

$$S_g^2 = \frac{\sum_j (K_j - 1) S_{jg}^2}{\sum_j (K_j - 1)} \quad (5)$$

and

$$S_{jg}^2 = \frac{\sum_{k=1}^{K_j} (\gamma_{jgk} - \bar{\gamma}_{jg})^2}{K_j - 1}. \quad (6)$$

Next, we divide the genes into two groups. The first group consists of the genes where $\hat{\gamma}_{1g} \geq \hat{\gamma}_{2g}$ and the remainder of the genes are kept in the second group. We group such that the tumor-type representing lines in our plot do not cross. Now, within each gene group, we again partition the genes into subgroups so that similarly expressed genes are grouped together. The

Self-Organizing Map (SOM) (Kohonen, 1987) analysis of variance approach is exploited for this partitioning. Then, within each of the subgroups, genes are ordered according to $|\hat{\gamma}_{1g} - \hat{\gamma}_{2g}|$. This further partitioning and ordering method confers suitable shapes to the tumor-type representing lines such that the user can quickly visualize the tumor-type discriminating power of the selected genes. Before generating the final plot we normalize the standardized average expression values $\hat{\gamma}_{jg}$ as follows:

$$\tilde{\gamma}_{jg} = \frac{\hat{\gamma}_{jg} - \min_{j,g}(\hat{\gamma}_{jg})}{\max_{j,g}(\hat{\gamma}_{jg}) - \min_{j,g}(\hat{\gamma}_{jg})} \quad (7)$$

Finally, the normalized expression values $\tilde{\gamma}_{jg}$ are plotted using parallel coordinates, where each parallel axis corresponds to a specific gene and each polyline corresponds to a specific tumor type. Each gene's subgroups are plotted in separate plots. Algorithm 1 specifies our formalized approach to gene visualization. The purpose of such plots is to qualitatively measure the performance of the gene selection process and to find the appropriate cutoff that reduces the number of false positives while keeping the number of true positives high.

The following results illustrate the usefulness of our visualization method provided in Algorithm 1. The

expression patterns of the marker genes associated with medulloblastoma survivor and failure groups is shown in Figs. 2 and 3. The solid and dotted lines represent the failure (death) and survivor (alive) groups, respectively. Genes are selected using the Wilcoxon method, which was previously described, wherein depending on the q-values, different numbers of genes are selected. In both Figs. 2 and 3, each individual graph represents a group of similarly expressed genes clustered together as specified in step 5 of Algorithm 1. Figs. 2 and 3 show 280 and 54 selected marker genes, respectively. We observe that within 280 selected genes in Fig. 2, many show similar expression patterns in both failure and survivor sample groups indicating that two sample groups are close to one another on the parallel axes. Since each axis represents a different gene, we conclude that many of the genes in Fig. 2 are falsely identified as marker genes (false positives). In comparison, the solid and dotted lines are far apart on most of the parallel axes in Fig. 3. This indicates that the average gene expression values of the selected 54 genes are quite different between the two groups of tissue samples. Thus, this visualization aids in selecting the correct threshold in the marker gene selection process.

Algorithm 1 (DATA) to visualize the expression pattern of the selected marker genes

DATA contains the expression levels of the marker genes for all the patient samples; where each row represents different gene expression values and each column represents different patient samples.

1. Sort the genes in descending order according to the values of q-values and select the top G genes from the sorted list.
 2. Estimate the average of the tumor-specific gene expression values $\bar{\gamma}_{jg}$ within any specific tissue sample type using Eq. (3)
 3. Obtain the standardized average gene expression values $\hat{\gamma}_{jg}$ using Eq. (4).
 4. Partition the genes into two groups: (i) C_1 where $\hat{\gamma}_{1g} \geq \hat{\gamma}_{2g}$ and (ii) C_2 where $\hat{\gamma}_{1g} < \hat{\gamma}_{2g}$.
 5. Within each group C_c ($c=1, 2$), again partition the gene expression values $\hat{\gamma}_{jg}$ into P clusters $\{C_{c1} \dots C_{cp}\}$ ($c=1, 2$) exploiting SOM, where each cluster consists of a group of similarly expressed genes.
 6. For each of the clusters obtained in the previous step:
 - a. Order the genes according to $|\hat{\gamma}_{1g} - \hat{\gamma}_{2g}|$.
 - b. Obtain $\tilde{\gamma}_{jg}$ by normalizing the standardized average expression values $\hat{\gamma}_{jg}$ using Eq. (7).
 - c. Plot the normalized average expression values $\tilde{\gamma}_{jg}$ using parallel coordinates, where each parallel axes corresponds to a specific gene and each polyline corresponds to a specific tissue sample type.
-

Figure 2. Expression patterns of the marker genes associated with medulloblastoma survivor and failure groups. Genes are selected using Wilcoxon method and FDR is controlled using q -values, where depending on the q -values, different numbers of genes are selected 280 genes.

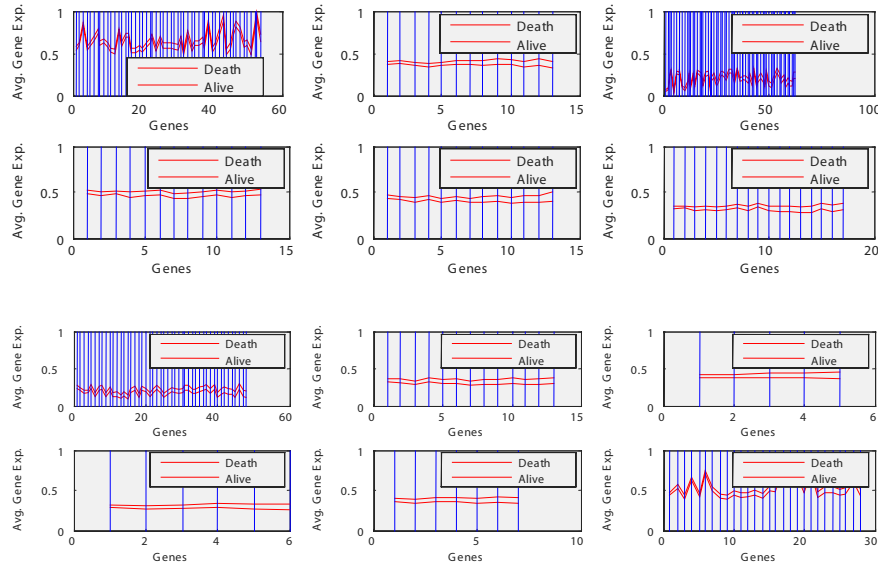

Figure 3. Expression patterns of the marker genes associated with medulloblastoma survivor and failure groups. Genes are selected using Wilcoxon method and FDR is controlled using q -values, where depending on the q -values, different numbers of genes are selected 54 genes.

FUTURE TRENDS

In this chapter, we estimate the tumor-specific gene expression measure exploiting an ANOVA model. We specify the model parameters as fixed effects; however, such specification may not be always appropriate. Rather, considering the model parameters as random

effects may be more appropriate for microarray dataset (Kerr et al., 2000). Thus, one possible improvement may consider all of the effects in our ANOVA model as random. Further, specifying the random effect parameters in a Bayesian framework provides a formal way of exploiting any prior knowledge about the parameter distribution, if available. We are currently in the process

of adopting a hierarchical Bayesian approach to our work following a few more recent relevant works by (Ibrahim et al., 2002, Lewin et al., 2006).

CONCLUSION

We attempted to estimate tumor-specific gene expression measures using an ANOVA model. These estimates are then used to identify differentially expressed marker genes. For evaluating the marker gene identification, we proposed a novel approach to visualize the average genes expression values for a specific tissue type. The proposed visualization plot is useful to qualitatively evaluate the performance of marker gene selection methods, as well as to locate the appropriate cutoffs in the selection process. The research in this chapter was supported in part through research grants [RG-01-0125, TG-04-0026] provided by the Whitaker Foundation with Khan M. Iftexharuddin as the principal investigator.

KEY TERMS

DNA Microarray: A collection of microscopic DNA spots, commonly representing single genes, arrayed on a solid surface by covalent attachment to chemically suitable matrices.

False Discovery Rate (FDR): Controls the expected proportion of false positives instead of controlling the chance of any false positives. An FDR threshold is determined from the observed p-value distribution from multiple single hypothesis tests.

Histologic Examination: The examination of tissue specimens under a microscope.

Kruskal-Wallis Test: A nonparametric mean test which can be applied if the number of sample groups is more than two, unlike the Wilcoxon Rank Sum Test.

Parallel Coordinates: A data visualization scheme that exploits 2D pattern recognition capabilities of humans. In this plot, the axes are equally spaced and are arranged parallel to one another rather than being arranged mutually perpendicular as in the Cartesian scenario.

q-values: A means to measure the proportion of FDR when any particular test is called significant.

Wilcoxon Rank Sum Test: A nonparametric alternative to the two sample t-test which is based on the order in which the observations from the two samples fall.

CNS Tumor Prediction Using Gene Expression Data Part II

INTRODUCTION

In this chapter, we propose a novel algorithm for characterizing a variety of CNS tumors. The proposed algorithm is illustrated with an analysis of an Affymetrix gene expression data from CNS tumor samples (Pomeroy et al., 2002). As discussed in the previous chapter entitled: CNS Tumor Prediction Using Gene Expression Data Part I, we used an ANOVA model to normalize the microarray gene expression measurements. In this chapter, we introduce a systemic way of building tumor prototypes to facilitate automatic prediction of CNS tumors.

BACKGROUND

DNA microarrays, also known as genome or DNA chips, have become an important tool for predicting CNS tumor types (Pomeroy et al., 2002, Islam et al., 2005, Dettling et al., 2002). Several researchers have shown that cluster analysis of DNA microarray gene expression data is helpful in finding the functionally similar genes and also to predict different cancer types. Eisen et al. (1998) used average linkage hierarchical clustering with correlation coefficient as the similarity measure in organizing gene expression values from microarray data. They showed that functionally similar genes group into the same cluster. Herwig et al. (1999) proposed a variant of the K-means algorithm to cluster genes of cDNA clones. Tomayo et al. (1999) used self-organized feature maps (SOFMs) to organize

genes into biologically relevant groups. They found that SOFMs reveal true cluster structure compared to the rigid structure of hierarchical clustering and the structureless K-means approach. Considering the many-to-many relationships between genes and their functions, Dembele et al. (2003) proposed a fuzzy C-means clustering technique. The central goal of these clustering procedures (Eisen et al., 1998, Herwig et al., 1999, Tomayo et al., 1999, Dembele et al., 2003) was to group genes based on their functionality. However, none of these works provide any systematic way of discovering or predicting tissue sample groups as we propose in our current work.

To identify tissue sample groups, Alon et al. (1999) proposed a clustering algorithm that uses a deterministic-annealing algorithm to organize the data in a binary tree. Alizadeh et al. (2000) demonstrated a successful molecular classification scheme for cancers from gene expression patterns by using an average linkage hierarchical clustering algorithm with Pearson's correlation as the similarity measure. However, no formal way of predicting the category of a new tissue sample is reported in (Alon et al., 1999, Alizadeh et al., 2000). Such class prediction problems were addressed by Golub et al. (1999) who used SOFMs to successfully discriminate between two types of human acute leukemia. Dettling et al. (2002) incorporated the response variables into gene clustering and located differentially expressed groups of genes from the clustering result. These gene groups were then used to predict the categories of new samples. However, none of the above-mentioned works (Dettling et al., 2002, Golub et al., 1999, Alon et al.,

1999, Alizadeh et al., 2000) considered the correlation among the genes in classifying and/or predicting tissue samples. Moreover, none of these provided any systematic way of handling the probable subgroups within the known groups. In this chapter, we consider both correlations among the genes and probable subgroups within the known groups by forming appropriate tumor prototypes. Further, a major drawback of these analyses (Dettling et al., 2002, Eisen et al., 1998, Herwig et al., 1999, Tomayo et al., 1999, Dembele et al., 2003, Golub et al., 1999, Alon et al., 1999, Alizadeh et al., 2000) is insufficient normalization. Although, most of these methods normalize the dataset to remove the array effects; they do not concentrate on removing other sources of variations present in the microarray data.

Our primary objective in this chapter is to develop an automated prediction scheme for CNS tumors, based on DNA microarray gene expressions of tissue samples. We propose a novel algorithm for deriving prototypes for different CNS tumor types, based on Affymetrix HuGeneFL microarray gene expression data from Pomeroy et al. (2002). In classifying the CNS tumor samples based on gene expression, we consider molecular information, such as the correlations among gene expressions and probable subgroupings within the known histological tumor types. We demonstrate how the model can be utilized in CNS tumor prediction.

CNS TUMOR PROTOTYPE FOR AUTOMATIC TUMOR DETECTION

The workflow to build the tumor prototypes is shown in Fig. 1. In the first step, we obtain the tumor-type-specific gene expression measures. Then, we identify the marker genes that are significantly differentially expressed among tissue types. Next, a visualization technique is used to analyze the appropriateness of the marker gene selection process. We organize the marker genes in groups so that highly correlated genes are grouped together. In this clustering process, genes are grouped based on their tumor-type-specific gene

expression measures. Then, we obtain eigengene expressions measures from each individual gene group by projection of gene expressions into the first few principal components. At the end of this step, we replace the gene expression measurements with eigengene expression values that conserve correlations between strongly correlated genes. We then divide the tissue samples of known tumor types into subgroups. The centroids of these subgroups of tissue samples with eigengene expressions represent the prototype of the corresponding tumor type. Finally, any new tissue sample is predicted as the tumor type of the closest centroid. This proposed novel prediction scheme considers both the correlation among the highly correlated genes and the probable phenotypic subgrouping within the known tumor types. These issues are often ignored in the literature for predicting tumor categories. The detail of the steps up to the identification of marker genes are provided in the previous chapter entitled: CNS Tumor Prediction Using Gene Expression Data Part I. In this section, we provide the details of the subsequent steps.

Now, we discuss the creation of the tumor prototypes using the tumor-specific expression values of our significantly differentially expressed marker genes identified in the previous step. Many of the marker genes are likely to be highly correlated. Such correlations of the genes affect successful tumor classification. However, this gene-to-gene correlation may provide important biological information. Hence, the inclusion of the appropriate gene-to-gene correlations in the tumor model may help to obtain a more biologically meaningful tumor prediction. To address this non-trivial need, we first group the highly correlated genes using the complete linkage hierarchical approach wherein correlation coefficient is considered as the pair-wise similarity measure of the genes. Next, for each of the clusters, we compute the principal components (PCs) and project the genes of the corresponding cluster onto the first 3 PCs to obtain eigengene expressions (Speed, 2003). Note that the PCs and the eigengene expressions are computed separately for each cluster. Such eigengenes encode the correlation information among

Figure 1. Simplified workflow to build the tumor prototypes

the highly correlated genes that are clustered together. Recently, molecularly distinct sub-grouping within the same histological tumor type has been reported (Taylor et al., 2005). To find a subgrouping within the same histological tumor type, we again use self-organizing maps (SOMs) (Kohonen, 1987) to cluster the tissue samples within each tumor group. This subgrouping within each group captures the possible genotypic variations within the same histological tumor type. Now, the prototype of any specific histological tumor type is composed of the centroid obtained from the corresponding SOM grid. Algorithm 1 shows our steps for building the tumor prototype.

To predict the tumor category of any new sample, we calculate the distances between the new sample and each of the prototype subgroups obtained using Algorithm 1. The category of the sample is predicted as that of the closest subgroup. The distance between the new sample and the x th subgroup, d_x , is calculated based on Euclidean distance as follows:

$$d_x = \sqrt{\sum_{k=1}^N (\bar{g}_{xk} - g_k)^2} \quad (1)$$

where \bar{g}_{xk} is the center value of k^{th} eigengene in the x^{th} subgroup, g_k is the expression measure of k^{th} eigengene of the new sample, and N is the total number of eigengenes. This distance measure deliberately ignores the non-representative correlations among the eigengene expressions since they are not natural and hence difficult to interpret.

Table 1 shows the efficacy of our model in classifying five categories of tissues simultaneously. Table 2 shows the performance comparison between our

proposed prediction scheme and the method adopted in (Pomeroy et al., 2002). We observe that our prediction scheme outperforms the other prediction method in all three cases. The most noticeable difference is with data group C where we obtain 100% prediction accuracy compared with 78% accuracy. More detailed results and discussion can be found in (Islam et al., 2006a, 2006b, 2006c).

FUTURE TRENDS

In this work, we estimated the tumor-specific gene expression measure exploiting an ANOVA model with the parameters as fixed effects. As discussed in the future trends section of the chapter entitled: CNS Tumor Prediction Using Gene Expression Data Part I, we may consider all of the effects in our ANOVA model as random and specify the random effect parameters in a Bayesian framework. Once the distributions of tumor-specific gene expression measures are obtained with satisfactory confidence, more representative tumor prototypes may be obtained and a more accurate tumor prediction scheme can be formalized. Representing the tumor prototypes with a mixture of Gaussian models may provide a better representation. In that case, finding the number of components in the mixture is another research question left for future work.

CONCLUSION

For automatic tumor prediction, we have proposed a novel algorithm for building CNS tumor prototypes

Algorithm 1 (DATA) to build tumor prototype

DATA contains the expression levels of the marker genes for all the patient samples; where each row represents different gene expression values and each column represents different patient samples.

1. Cluster genes into K partitions, $C = \{C_1, C_2, \dots, C_k\}$, using Complete Linkage Hierarchical approach and *correlation coefficient* as the pair wise similarity measure.
 2. For each cluster C_i
 - a. Compute the principal components (PCs).
 - b. If the cluster cardinality is greater than 3, project the genes onto the first 3 PCs else project the genes onto the first PC.
Note: the projected vectors are considered as eigengene expressions.
 3. Considering the eigengene expressions as feature vectors, cluster each histological tumor group into subgroups exploiting SOM.
 4. The set of centroid of the corresponding SOM grid is designated as the tumor prototype of that particular histological tumor type.
-

Table 1. Confusion matrix for five categories of tumor samples

| | Medulloblastoma | Glioma | AT/RTs | Normal | PNET | Recall |
|-----------------|-----------------|--------|--------|--------|------|--------|
| Medulloblastoma | 9 | 0 | 1 | 0 | 0 | 0.9 |
| Glioma | 0 | 9 | 1 | 0 | 0 | 0.9 |
| AT/RTs | 0 | 0 | 10 | 0 | 0 | 1.0 |
| Normal | 0 | 0 | 1 | 3 | 0 | 0.75 |
| PNET | 0 | 1 | 0 | 0 | 7 | 0.88 |
| Precision | 1.0 | 0.9 | 0.77 | 1.0 | 1.0 | |

Overall Classification Accuracy: 90%

Table 2. Comparison table

| Data Group | Number of Categories | Number of Samples | Classification Accuracy (our method) | Classification Accuracy (Pomeroy et al., 2002) |
|------------|----------------------|-------------------|--------------------------------------|--|
| A | 5 | 42 | 90% | 83% |
| B | 2 | 34 | 100% | 97% |
| C | 2 | 60 | 100% | 78% |

based on Affymetrix microarray gene expression values. We derived prototypes for different histological tumor types considering their genotype heterogeneity within groups. The eigengenes encode the correlations among gene expressions into the prototypes. Also, the eigen-gene expression measures are derived from estimated tumor-specific gene expression measures that are free from other unwanted sources of variations. We proposed a novel, seamless procedure that integrates normalization and tumor prediction considering both probable subgroupings within known tumor types and probable correlations among genes. The strong compliance of our results with the current molecular classification of the available tumor types suggests that our proposed model and its unique solution have significant practical value for automatic CNS tumor detection.

The research in this chapter was supported in part through research grants [RG-01-0125, TG-04-0026] provided by the Whitaker Foundation with Khan M. Iftekharuddin as the principal investigator.

KEY TERMS

DNA Microarray: Also known as a DNA chip, it is a collection of microscopic DNA spots, commonly representing single genes, arrayed on a solid surface by covalent attachment to chemically suitable matrices.

False Discovery Rate (FDR): FDR controls the expected proportion of false positives instead of controlling the chance of any false positives. A FDR threshold is determined from the observed p-value distribution from multiple single hypothesis tests.

Histologic Examination: The examination of tissue specimens under a microscope.

Kruskal-Wallis Test: This test is a nonparametric mean test which can be applied if the number of sample group is more than two, unlike the Wilcoxon Rank Sum Test.

Parallel Coordinates: A multidimensional data visualization scheme that exploits 2D pattern recognition capabilities of humans. In this plot, the axes are equally spaced and are arranged parallel to one another rather than being arranged mutually perpendicular as in the Cartesian scenario.

q-Values: A means to measure the proportion of FDR when any particular test is called significant.

Self-Organizing Maps (SOMs): A method to learn to cluster input vectors according to how they are naturally grouped in the input space. In its simplest form, the map consists of a regular grid of units and the units learn to represent statistical data described by model vectors. Each map unit contains a vector used to represent the data. During the training process, the

model vectors are changed gradually and then the map forms an ordered non-linear regression of the model vectors into the data space.

Wilcoxon Rank Sum Test: A nonparametric alternative to the two sample t-test which is based on the order in which the observations from the two samples fall.

Combining Classifiers and Learning Mixture-of-Experts

Lei Xu

Chinese University of Hong Kong, Hong Kong & Peking University, China

Shun-ichi Amari

Brain Science Institute, Japan

INTRODUCTION

Expert combination is a classic strategy that has been widely used in various problem solving tasks. A team of individuals with diverse and complementary skills tackle a task jointly such that a performance better than any single individual can make is achieved via integrating the strengths of individuals. Started from the late 1980' in the handwritten character recognition literature, studies have been made on combining multiple classifiers. Also from the early 1990' in the fields of neural networks and machine learning, efforts have been made under the name of ensemble learning or mixture of experts on how to learn jointly a mixture of experts (parametric models) and a combining strategy for integrating them in an optimal sense.

The article aims at a general sketch of two streams of studies, not only with a re-elaboration of essential tasks, basic ingredients, and typical combining rules, but also with a general combination framework (especially one concise and more useful one-parameter modulated special case, called α -integration) suggested to unify a number of typical classifier combination rules and several mixture based learning models, as well as max rule and min rule used in the literature on fuzzy system.

BACKGROUND

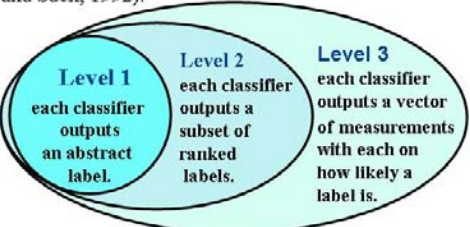

Both streams of studies are featured by two periods of developments. The first period is roughly from the late 1980s to the early 1990s. In the handwritten character recognition literature, various classifiers have been developed from different methodologies and different features, which motivate studies on combining multiple classifiers for a better performance. A systematical effort on the early stage of studies was made in (Xu,

Krzyzak & Suen, 1992), with an attempt of setting up a general framework for classifier combination. As re-elaborated in Tab.1, not only two essential tasks were identified and a framework of three level combination was presented for the second task to cope with different types of classifier's output information, but also several rules have been investigated towards two of the three levels, especially with Bayes voting rule, product rule, and Dempster-Shafer rule proposed. Subsequently, the rest one (i.e., rank level) was soon studied in (Ho, Hull, & Srihari, 1994) via Borda count.

Interestingly and complementarily, almost in the same period the first task happens to be the focus of studies in the neural networks learning literature. Encountering the problems that there are different choices for the same type of neural net by varying its scale (e.g., the number of hidden units in a three layer net), different local optimal results on the same neural net due to different initializations, studies have been made on how to train an ensemble of diverse and complementary networks via cross-validation-partitioning, correlation reduction pruning, performance guided re-sampling, etc, such that the resulted combination produces a better generalization performance (Hansen & Salamon, 1990; Xu, Krzyzak, & Suen, 1991; Wolpert, 1992; Baxt, 1992, Breiman, 1992&94; Drucker, et al, 1994). In addition to classification, this stream also handles function regression via integrating individual estimators by a linear combination (Perrone & Cooper, 1993). Furthermore, this stream progresses to consider the performance of two tasks in Tab.1 jointly in help of the mixture-of-expert (ME) models (Jacobs, et al, 1991; Jordan & Jacobs, 1994; Xu & Jordan, 1993; Xu, Jordan & Hinton, 1994), which can learn either or both of the combining mechanism and individual experts in a maximum likelihood sense.

Two stream studies in the first period jointly set up a landscape of this emerging research area, together

Table 1. Essential tasks and their implementations

| Two Tasks (a quotation from Xu, Krzyzak and Suen, 1992) | | |
|---|--|---|
| <p>Task 1: “How many and what type of classifiers should be used for a specific application?, and for each classifier what type of features should we use?, as well as other problems that are related to the construction of those individual and complementary classifier”.</p> <p>Task 2: “How to combine the results from different existing classifiers so that a better result can be obtained?”</p> | | |
| Two Styles of Implementations | | |
| Two Stage Implementation | Joint Implementation | |
| <ul style="list-style-type: none"> • Task 1 is completed in advance, with the resulted classifiers being diverse and complementary. • Perform Task 2 in one of three levels (Xu, Krzyzak and Suen, 1992).  | Two tasks made jointly or alternatively | |
| | under a same criterion | others |
| | <ul style="list-style-type: none"> • Mixture of experts (ME) (Jacobs, et al, 1991; Jordan & Jacobs, 1994); • Alternative ME (Xu & Jordan, 1993; Xu, Jordan & Hinton, 1994); • EM-RBF (Xu, 1998) • Three layer nets, etc. | <p>Stacking, Boosting, ..., etc (Breiman, 1992&94; Wolpert, 1992)</p> |

with a number of typical topics or directions. Thereafter, further studies have been further conducted on each of these typical directions. First, theoretical analyses have been made for deep insights and improved performances. For examples, convergence analysis on the EM algorithm for the mixture based learning are conducted in (Jordan & Xu, 1995; Xu & Jordan, 1996). In Tumer & Ghosh (1996), the additive errors of posteriori probabilities by classifiers or experts are considered, with variances and correlations of these errors investigated for improving the performance of a sum based combination. In Kittler, et al (1998), the effect of these errors on the sensitivity of sum rule vs product rule are further investigated, with a conclusion that summation is much preferred. Also, a theoretical framework is suggested for taking several combining rules as special cases (Kittler, 1998), being unaware of that this framework is actually the mixture-of-experts model that was proposed firstly for combining multiple function regressions in (Jacobs, et al, 1991) and then for combining multiple classifiers in (Xu & Jordan, 1993). In addition, another theoretical study is made on six classifier fusion strategies in (Kuncheva, 2002). Second, there are further studies on Dempster-Shafer rule (Al-Ania, 2002) and other combining methods such as rank based, boosting based, as well as local

accuracy estimates (Woods, Kegelmeyer, & Bowyer, 1997). Third, there are a large number of applications. Due to space limit, details are referred to Ranawana & Palade (2006) and Sharkey & Sharkey (1999).

A GENERAL ARCHITECTURE, TWO TASKS, AND THREE INGREDIENTS

We consider a general architecture shown in Fig.1. There are $\{e_j(x)\}_{j=1}^k$ experts with each $e_j(x)$ as either a classifier or an estimator. As shown in Tab.2, a classifier outputs one of three types of information, on which we have three levels of combination. The first two can be regarded as special cases of the third one that outputs a vector of measurements. A typical example is $[p_j(1|x), \dots, p_j(m|x)]^T$ with each $1 \geq p_j(\ell|x) \geq 0$ expressing a posteriori probability that x is classified to the ℓ -th class. Also, $p_j(\ell|x) = p_j(y = \ell|x)$ can be further extended to $p_j(y|x)$ that describes a distribution for a regression $x \rightarrow y \in R^m$. In Figure 1, there is also a gating net that generates signals $\{\alpha_j(x)\}_{j=1}^k$ to modulate experts by a combining mechanism $M(x)$.

Figure 1. A general architecture for expert combination

Table 2. Three levels of combination

| Three Rules for Combination on Level 3 | | |
|--|--|--|
| Sum rule (Bayes Voting) | Product rule | Dempster-Shafer rule |
| <p>Given k classifiers, the j-th classifier classifies x to y with a probability $p_j(y x) = p(x \in C_y e_j(x))$, we sum up to get a combination</p> $p(y x) = \frac{1}{k} \sum_{j=1}^k p_j(y x)$ <p>See eqn.(4) in (Xu, Krzyzak and Suen, 1992)</p> | <p>If k classifiers are independent, another combination is given by</p> $p(x \in C_y) = \frac{\prod_{j=1}^k p(x \in C_y e_j(x))}{\prod_{j=1}^k p(x \in C_y)}$ <p>or concisely</p> $p(y x) = p^{1-k}(y) \prod_{j=1}^k p_j(y x)$ <p>See eqn.(31) in (Xu, Krzyzak and Suen, 1992)</p> | <p>$bel(A) = \sum_{B \subseteq A} m(B)$</p> $m(A) = \frac{\sum_{x \cap y = A, A \neq \emptyset} m_x(X) m_y(Y)}{\sum_{x \cap y \neq \emptyset} m_x(X) m_y(Y)}$ <p>A_i denotes $x \in C_i$, $\theta = \{A_1, \dots, A_m\}$ if $e_j(x) = \ell_i$, $m_j(A_i) = \epsilon_r^{(j)}$ $\neg A_i = \theta - \{A_i\}$ $m_j(\neg A_i) = \epsilon_r^{(j)}$ $m_j(\theta) = 1 - \epsilon_r^{(j)} - \epsilon_s^{(j)}$</p> <p>See Sec.VI in (Xu, Krzyzak and Suen, 1992)</p> |

Based on this architecture, two essential tasks of expert combination could be still quoted from (Xu, Krzyzak & Suen, 1992) with a slight modification on Task 1, as shown in Tab.1, that the phrase ‘for a specific application?’ should be deleted in consideration of the previously introduced studies (Hansen & Salamon, 1990; Xu, Krzyzak, & Suen, 1991; Wolpert, 1992; Baxt, 1992; Breiman, 1992&94; Drucker, et al, 1994; Tumer & Ghosh, 1996).

Insights can be obtained by considering three basic ingredients of two streams of studies, as shown in Fig.2. Combinatorial choices of different ingredients lead to different specific models for expert combination, and differences in the roles by each ingredient highlight the different focuses of two streams. In the stream

of neural networks and machine learning, provided with a structure for each $e_j(x)$, a gating structure, and a combining structure $M(x)$, all the rest unknowns are determined under guidance of a learning theory in term of minimizing an error cost. Such a minimization is implemented via an optimizing procedure by a learning algorithm, based on a training set $\{x_t, y_t\}_{t=1}^N$ that teaches a target y_t for each mapping $x_t \rightarrow R^m$. While in the stream of combining classifiers, all $\{p_j(y|x)\}_{j=1}^k$ are known without unknowns left to be specified. Also, M is designed according to certain heuristics or principles, with or without help of a training set, and studies are mainly placed on developing and analyzing different combining mechanisms, for which we will further dis-

cuss subsequently. The final combining performance is empirically evaluated by the misclassification rate, but there is no effort yet on developing a theory for one M that minimizes the misclassification rate or a cost function, though there are some investigations on how estimated posteriori probabilities can be improved by a sum rule and on error sensitivity of estimated posteriori probabilities (Tumer & Ghosh, 1996; Kittler, et al, 1998). This under-explored direction also motivate future studies subsequently.

f -COMBINATION

The arithmetic, geometric, and harmonic mean of non-negative number $b_j \geq 0, j = 1, \dots, k$ has been further extended into one called:

$$f\text{-mean } m_f = f^{-1}\left(\sum_{j=1}^k \alpha_j f(b_j)\right),$$

where $f(r)$ is a monotonic scalar function, and

$$\alpha_j > 0 \sum_{j=1}^k \alpha_j = 1$$

(Hardy, Littlewood, & Polya, 1952).

We can further generalize this f -mean to the general architecture shown in Fig.1, resulting in the following f -combination:

$$M(x) = f^{-1}\left(\sum_{j=1}^k \alpha_j(x) f(p_j(y|x))\right), \text{ or}$$

$$f(M(x)) = \sum_{j=1}^k \alpha_j(x) f(p_j(y|x))$$

where

$$\alpha_j > 0 \sum_{j=1}^k \alpha_j(x) = 1.$$

In the following, we discuss to use it as a general framework to unify not only typical classifier combining rules but also mixture-of-expert learning and RBF net learning, as shown in Tab.3.

We observe the three columns for three special cases of $f(r)$. The first column is the case $f(r) = r$, we return to the ME model:

$$M(x) = \sum_{j=1}^k \alpha_j(x) p_j(y|x),$$

which was proposed firstly for combining multiple regressions in (Jacobs, et al, 1991) and then for combining classifiers in (Xu & Jordan, 1993). For different special cases of $\alpha_j(x)$, we are lead to a number of existing typical examples. As already pointed out in (Kittler, et al, 1998), the first three rows are four typical classifier combining rules (the 2nd row directly applies to the min-rule too). The next three rows are three types of ME learning models, and a rather systematic summary

Figure 2. Three basic ingredients

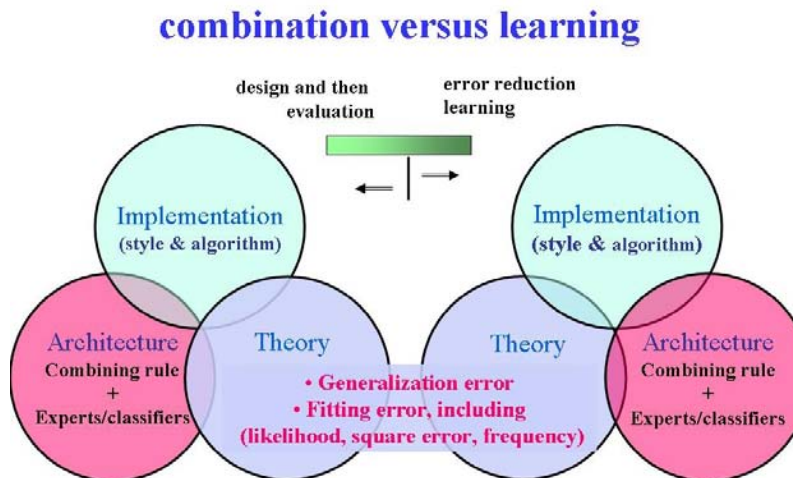

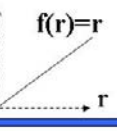

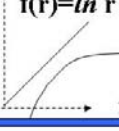

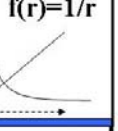

Table 3. Typical examples (including several existing rules and potential topics)

| $f(M) \quad f(r)$ $\alpha_j(x)$ |  |  |  |
|---|---|--|---|
| $\alpha_j(x) = 0$, except $\alpha_j(x) = 1$ $j = \begin{cases} \text{argmax}_j p_j(y x), (a), \\ \text{argmin}_j p_j(y x), (b). \end{cases}$ | (a) max-rule (b) min-rule | (a) max-rule (b) min-rule | (a) max-rule (b) min-rule |
| $\alpha_j(x) = 1/k$ | Average Bayes or Bayes voting (Xu, Krzyzak & Suen, 1992) | Product rule (Xu, Krzyzak & Suen, 1992; Kittler, et al, 1998; Hinton, 2002) | Harmonic mean |
| $\alpha_j(x) = \alpha_j = \frac{\sigma_j^{-2}}{\sum_{j=1}^k \sigma_j^{-2}}$ | Mixture using variances (MUV) (Perrone&Cooper, 1993) | To be explored | To be explored |
| $\alpha_j(x) = \frac{e^{g_j(x, \phi)}}{\sum_{j=1}^k e^{g_j(x, \phi)}}$ | Mixture-of-experts (ME) (Jacobs, et al, 1991) | To be explored | To be explored |
| $\alpha_j(x) = \frac{\beta_j p(x \phi_j)}{\sum_{j=1}^k \beta_j p(x \phi_j)}$ | Alternative ME (Xu, Jordan& Hinton, 1994) | To be explored | To be explored |
| $\alpha_j(x) = \frac{\beta_j G(x \mu_j, \Sigma_j)}{\sum_{j=1}^k \beta_j G(x \mu_j, \Sigma_j)}$ subject to $\beta_j / \sqrt{ \Sigma_j } = \text{const}$ | Extended Normalized RBF (Xu, 1998) | To be explored | To be explored |
| $\alpha_j(x) = \sigma_j^{-2}(x) / \sum_{j=1}^k \sigma_j^{-2}(x)$ | Belief net based MUV (Lee, et al, 2006) | To be explored | To be explored |

is referred to Sec. 4.3 in (Xu, 2001). The last row is a recent development of the 3rd row.

The 2nd row of the 2nd column is the geometric mean:

$$M(x) = \sqrt[k]{\prod_{j=1}^k p_j(y|x)},$$

which is equal to the product rule (Xu, Krzyzak and Suen, 1992; Kittler, et al, 1998, Hinton, 2002) if each a priori is equal, i.e., $\alpha_j(x) = 1/m$. Generally if $\alpha_j(x) \neq 1/m$, there is a difference by a scaling factor $\alpha_j(x)^{1/k-1}$. The product rule works in a probability theory sense under a condition that classifiers are mutually independent. In (Kittler, et al, 1998), attempting to discuss a number of rules under a unified system, the sum rule is approximately derived from the product rule, under an extra condition that is usually difficult to satisfy. Actually, such an imposed link between the product rule and the sum rule is unnecessary, the sum:

$$M(x) = \sum_{j=1}^k \alpha_j(x) p_j(y|x)$$

is just a marginal probability

$$\sum_{j=1}^k p(y, j|x),$$

which is already in the framework of probability theory. That is, both the sum rule and the product rule already coexist in the framework of probability theory.

On the other hand, it can be observed that the sum:

$$\sum_{j=1}^k \alpha_j(x) \ln p_j(y|x)$$

is dominated by a $p_j(y|x)$ if it is close to 0. That is, this combination expects that every expert should cast enough votes, otherwise the combined votes will be still very low just because there is only one that casts a very low vote. In other words, this combination can

be regarded as a relaxed logical AND that is beyond the framework of probability theory when $\alpha_j(x) \neq 1/m$. However, staying within the framework of probability theory does not mean that it is better, not only because it requires that classifiers are mutually independent, but also because there lacks theoretical analysis on both rules in a sense of classification errors, for which further investigations are needed.

In Tab.2, the 2nd row of the third column is the harmonic mean. It can be observed that the problem of combining the degrees of support is changed into a problem of combining the degrees of disagree. This is interesting. Unfortunately, efforts of this kind are seldom found yet. Exceptionally, there are also examples that can not be included in the f -combination, such as Dempster-Shafer rule (Xu, Krzyzak and Suen, 1992; Al-Ania, 2002) and rank based rule (Ho, Hull, Srihari, 1994).

α -INTEGRATION

After completed the above f -combination, the first author becomes aware of the work by (Hardy, Littlewood, & Polya, 1952) through one coming paper (Amari, 2007) that studies a much concise and more useful one-parameter modulated special case called α -integration. With help of a concrete mathematical foundation from an information geometry perspective. Imposing an additional but reasonable nature that the f -mean should be linear scale-free, i.e.:

$$cm_f = f^{-1}(\sum_{j=1}^k \alpha_j f(cb_j))$$

for any scale c , alternative choices of $f(r)$ reduces into the following only one:

$$f_\alpha(r) = \begin{cases} r^{0.5(1-\alpha)}, & \alpha \neq 1, \\ \ln r, & \alpha = 1. \end{cases}$$

It is not difficult to check that

$$f_\alpha(r) = \begin{cases} r, & \alpha = -1, \\ \ln r, & \alpha = 1, \\ 1/r, & \alpha = 3. \end{cases}$$

Thus, the discussions on the examples in Tab.2 are applicable to this $f_\alpha(r)$. Moreover, the first row in Tab.2 holds when $\alpha = -\infty$ and $\alpha = +\infty$ for whatever a gating net, which thus includes two typical operators of the fuzzy system as special case too. Also, the family is systematically modulated by a parameter $-\infty \leq \alpha \leq +\infty$, which provides not only a spectrum from the most optimistic integration to the most pessimistic integration as varying from $\alpha = -\infty$ to $\alpha = +\infty$ but also a possibility of adapting α for a best combining performance.

Furthermore, Amari (2007) also provides a theoretical justification that α -integration is optimal in a sense of minimizing a weighted average of α -divergence. Moreover, it provides a potential road for studies on combining classifiers and learning mixture models from the perspective of information geometry.

FUTURE TRENDS

Further studies are expected along several directions as follows:

- Empirical and analytical comparisons on performance are needed for those unexplored or less explored items in Tab.2.
- Is there a best structure for $\alpha_j(x)$? comparisons need to be made on different types of $\alpha_j(x)$, especially the ones by the MUV type in the last row and the ME types from the 4th to the 7th rows,
- Is it necessary to relax the constraint:

$$\alpha_j(x) > 0, \sum_{j=1}^k \alpha_j(x) = 1,$$

e.g., removing non-negative requirement and to relax the distribution $p_j(y|x)$ to other types of functions?

- How weights $\alpha_j(x)$ can be learned under a generalization error bound.
- As discussed in Fig.2, classifier combination and mixture based learning are two aspects with different features. How to let each part to take their best roles in an integrated system?

CONCLUSION

Updating the purpose of (Xu, Krzyzak & Suen, 1992), the article provides not only a general sketch of studies

on combining classifiers and learning mixture models, but also a general combination framework to unify a number of classifier combination rules and mixture based learning models, as well as a number of directions for further investigations.

KEY TERMS

Conditional Distribution $p(y|x)$: Describes the uncertainty that an input x is mapped into an output y that simply takes one of several labels. In this case, x is classified into the class label y with a probability $p(y|x)$. Also, y can be a real-valued vector, for which x is mapped into y according density distribution $p(y|x)$.

Classifier Combination: Given a number of classifiers, each classifies a same input x into a class label, and the labels maybe different for different classifiers. We seek a rule $M(x)$ that combines these classifiers as a new one that performs better than anyone of them.

Sum Rule (Bayes Voting): A classifier classifies x to a label y can be regarded as casting one vote to this label, a simplest combination is to count the votes received by every candidate label. The j -th classifier classifies x to a label y with a probability $p_j(y|x)$ means that one vote is divided to different candidates in fractions. We can sum up:

$$\sum_j p_j(y|x)$$

to count the votes on a candidate label y , which is called Bayes voting since $p(y|x)$ is usually called Bayes posteriori probability.

Product Rule: When k classifiers $\{e_j(x)\}_{j=1}^k$ are mutually independent, a combination is given by

$$p(x \in C_y | x) = p(x \in C_y) \frac{\prod_{j=1}^k p(x \in C_y | e_j(x))}{\prod_{j=1}^k p(x \in C_y)}$$

or concisely

$$p(y | x) = p^{1-k}(y) \prod_{j=1}^k p_j(y | x),$$

which is also called product rule.

Mixture of Experts: Each expert is described by a conditional distribution $p_j(y | x)$ either with y taking one of several labels for a classification problem or with y being a real-valued vector for a regression problem. A combination of experts is given by:

$$M(x) = \sum_{j=1}^k \alpha_j(x) p_j(y | x), \quad \alpha_j(x) = p(j|x) > 0, \quad \sum_{j=1}^k \alpha_j(x) = 1,$$

which is called a mixture-of-experts model. Particularly, for y in a real-valued vector, its regression form is

$$E(y | x) = \sum_{j=1}^k \alpha_j(x) f_j(x), \quad f_j(y) = \int y p_j(y | x) dy.$$

f-Mean: Given a set of non-negative numbers

$b_j \geq 0, j = 1, \dots, k$, the f -mean is given by:

$$m_f = f^{-1}(\sum_{j=1}^k \alpha_j f(b_j)),$$

where $f(r)$ is a monotonic scalar function and

$$\alpha_j > 0 \sum_{j=1}^k \alpha_j = 1.$$

Particularly, one most interesting special case is that $f(r)$ satisfies

$$cm_f = f^{-1}(\sum_{j=1}^k \alpha_j f(cb_j))$$

for any scale c , which is called f_a -mean.

Performance Evaluation Approach: It usually works in the literature on classifier. Combination, with a chart flow that considering a set of classifiers $\{e_j(x)\}_{j=1}^k \rightarrow$ designing a combining mechanism $M(x)$ according to certain principles \rightarrow evaluating performances of combination empirically via misclassification rates, in help of samples with known correct labels.

Error-Reduction Approach: It usually works in the literature on mixture based learning, where what needs to be pre-designed is the structures of classifiers or experts, as well as the combining structure $M(x)$ with unknown parameters. A cost or error measure is evaluated via a set of training samples, and then minimized through learning all the unknown parameters.

Commonsense Knowledge Representation I

Phillip Ein-Dor

Tel-Aviv University, Israel

C

INTRODUCTION

Significant advances in artificial intelligence, including machines that play master level chess, or make medical diagnoses, highlight an intriguing paradox. While systems can compete with highly qualified experts in many fields, there has been much less progress in constructing machines that exhibit simple commonsense, the kind expected of any normally intelligent child. As a result, commonsense has been identified as one of the most difficult and important problems in AI (Doyle, 1984; Waltz, 1982).

BACKGROUND

The Importance of Commonsense¹

It may be useful to begin by listing a number of reasons why Commonsense is so important:

1. Any general natural language processor must possess the commonsense that is assumed in the text.
2. In building computerized systems, many assumptions are made about the way in which they will be used and the users' background knowledge. The more commonsense that can explicitly be built into systems, the less will depend on the implicit concurrence of the designer's commonsense with that of the user.
3. Many expert systems have some commonsense knowledge built into them, much of it reformulated time and again for similar systems. It would be advantageous if commonsense knowledge could be standardized for use in different systems.
4. Commonsense has a large element that is environment and culture specific. A study and formalization of commonsense knowledge may permit people of different cultures to better understand one another's assumptions.

Defining Commonsense

No attempt will be made here to define commonsense rigorously. Intuitively, however, commonsense is generally meant to include the following capabilities, as defined for any given culture:

- a. knowing the generally known facts about the world,
- b. knowing, and being able to perform, generally performed behaviors, and to predict their outcomes,
- c. being able to interpret or identify commonly occurring situations in terms of the generally known facts – i.e. to understand what happens,
- d. the ability to relate causes and effects,
- e. the ability to recognize inconsistencies in descriptions of common situations and behaviors and between behaviors and their situational contexts,
- f. the ability to solve everyday problems.

In summary, commonsense is the knowledge that any participant in a culture expects any other participant in that culture to possess, as distinct from specialized knowledge that is possessed only by specialists.

The necessary conditions for a formalization to lay claim to representing commonsense are implicit in the above definition; a formalism must exhibit at least one of the attributes listed there. Virtually all work in the field has attempted to satisfy only some subset of the commonsense criteria.

COMMONSENSE REPRESENTATION FORMALISMS

In AI research, work on common sense is generally subsumed under the heading of Knowledge Representation. The objective of this article is to survey the various formalisms that have been suggested for representing commonsense knowledge.

Four major knowledge representation schemes are discussed in the literature - production rules, semantic nets, frames, and logic. Production systems are frequently adopted in building expert systems. Virtually all the discussions of commonsense representations, however, are in terms of semantic net, frame-like, or logic systems. These schemes are applied within three main paradigms for commonsense representation—propositional, truth maintenance, and dispositional (see Figure 1). Very briefly, propositional models are descriptions of representations of things or concrete facts. When the knowledge represented is imprecise or variable, propositional formalisms are no longer sufficient and one needs to consider the beliefs about the world engendered by the system's current state of knowledge, and to allow for changes in those beliefs as circumstances dictate; this is the nature of belief or truth maintenance systems. Finally, when the knowledge is both imprecise and not factual, but relates rather to feelings, insights and understandings, the dispositional representations are evoked.

Within each representational paradigm, there are a number of specific formalisms. Figure 1 indicates the existence of eight different knowledge representation formalisms. Each of these formalisms is presented via discussion of one or more representatives.

The need for different types of formalisms, the difficulty in representing multiple domain knowledge, psychological theories of various levels of conscious-

ness, the physiological evidence of different levels of the brain and their association with specific functions, the functional specialization of specific areas of the brain, and similar evidence concerning the two sides of the brain all support the view of the mind, or self, as composed of a considerable number of cooperating subagents, to which Minsky (1981) refers as a society of mind. It is useful to keep this concept in mind while studying the variety of representation schemes; it suggests that a number of such formalisms may coexist in any rational agent and little can be gained by attempts to choose the “right” formalism in any general sense.

PROPOSITIONAL MODELS

Virtually all the propositional models of commonsense knowledge are perceived as consisting of nodes that are associated with words or tokens representing concepts. The nodes are hierarchically structured, with lower level nodes elaborating or representing instantiations of higher-level nodes; the higher-level nodes impart their properties to those below them, which are said to inherit those properties. Thus, all the propositional models are hierarchically structured networks consisting of nodes and arcs joining the nodes. From this point, the representational structures begin to diverge according to the distribution of information between the arcs and the nodes. At one extreme, nodes are self-contained

Figure 1. Commonsense knowledge representation formalisms

descriptions of concepts with only hierarchical relations between concepts expressed in the arcs; frames and scripts are of this nature. At the other extreme, nodes contain only names and the descriptive content resides in a multiplicity of types of relations, which give meaning to the names. This last form is generally referred to as a semantic net. Between the extremes lie representations in which the descriptive knowledge is distributed between nodes and relations.

The representations described may be discussed as theoretical models or as computer implementations, which generally derive from one of the theoretical models (see Commonsense Knowledge Representation II - Implementation).

Semantic Nets

Semantic nets were developed to represent propositions and their syntactic structure rather than the knowledge contained in the propositions. A semantic net consists of triples of nodes, arcs joining nodes, and labels (Rich, 1983). The words of a proposition are contained in the nodes while its syntactic structure is captured by the labeled arcs.

Frames

Within the community utilizing frames (or schema), it seems to be universally agreed that frames define concepts via the contents of slots, which specify components of the concepts. The content of a slot may be an instantiation, a default or usual value, a condition, or a sub-schema. The last of these slot contents generates the generally accepted hierarchical nature of concept representations.

Scripts

In his seminal paper on frames, Minsky (1975) suggests that frames are not exactly the same as Schank's (1981) scripts. The major difference is in the concepts represented. Scripts describe temporal sequences of events represented by the sequence of slots in a script. Here the slot structure is significant. For frames describing objects the exact order of slots is probably not significant. The temporal ordering of slots is necessary in many other representations, including those for most behaviors.

In summary, frames, scripts, and semantic nets are logically equivalent. All three are hierarchies consisting of nodes and relations; they are differentiated by the location of information in the network. Scripts are further differentiated by the temporal and causal ordering of slots within nodes.

Predicate Calculus

The first order predicate calculus is a method for representing and processing propositional knowledge and was designed expressly for that purpose. There are many workers in the field who view this formalism as the most appropriate for commonsense knowledge representation.

In discussing logic as a vehicle for knowledge representation, one should distinguish between the use of logic as the representational formalism, and the use of logistic languages for implementation. Logistic languages can implement any representational formalism, logistic or other. Another distinction that needs to be made is between the use of logic for inference and its use for representation (Hayes, 1979). Thus, one might apply logical inference to any knowledge representation, provided that it is amenable to that kind of manipulation; knowledge expressed in predicate calculus is the most amenable to such manipulation.

A vigorous debate in AI centered on the choice of frames or logic for commonsense knowledge representation. In favor of frames were those who attempted to implement knowledge representation schemes (cf. Hayes, 1979). The argument is twofold: first, logistic formalisms do not have sufficient expressive power to adequately represent commonsense knowledge. This applies particularly to the dynamic adjustment of what is held to be true as new information is acquired. Classical logic does not allow for reinterpretation as new facts are learned - it is monotonic. Secondly, this argument posits that human knowledge representation does not follow the rules of formal logic, so that logic is psychologically inadequate in addition to being expressively inadequate.

The logicians reply to the first argument is that anything can be expressed in logic, but this may sometimes be difficult; this school does not agree to the claim of greater expressive power for the frame paradigm. Hayes (1979) claimed that "most of 'frames' is just a new syntax for parts of first-order logic". Thus, all the representational formalisms seem to have much in

common, even if they are not completely equivalent. The reply to the second argument is that the object of study is Artificial Intelligence so that the formalisms adopted need not resemble human mechanisms.

One point of agreement that seems to have emerged between the two sides is that the classical predicate calculus indeed lacks sufficient expressive power. Evidence of this is a number of attempts to expand the logical formalisms in order to provide sufficient expressiveness, especially by alleviating some of the restrictions of monotonicity.

The essence of monotonicity is that if a theory A is expanded by additional axioms to become B, then all the theorems of A are still theorems of B. Thus, conclusions in monotonic logic are irreversible and this constraint must be relaxed if a logical inference system is to be able to reevaluate its conclusions on learning new facts. The conclusions of a non-monotonic logic are regarded as beliefs or dispositions based on what is currently known, and amenable to change if necessary.

The attempts to overcome the limitations of monotonicity include non-monotonic reasoning McCarthy (1980), non-monotonic logics (McDermott and Doyle, 1980; Reiter 1980), fuzzy logic (Zadeh, 1983), and a functional approach (Levesque, 1984) represented by the KL-One (Woods, 1983) and KRYPTON languages (Brachman et al., 1983). It should be noted that non-monotonic logic proceeds not by changing the logic representation, but rather by strengthening the reasoning by which representations are evaluated.

LOGISTIC REPRESENTATIONS: BELIEF MAINTENANCE SYSTEMS

Fuzzy Logic (Zadeh, 1983)

The extensive work by Zadeh in applying fuzzy logic to knowledge representation is based on the premise that predicate calculus is inadequate for commonsense knowledge representation because it does not allow for fuzzy predicates (e.g. small, cheap) or fuzzy quantifiers (e.g. many, most) as in the phrase “most small birds fly”.

Fuzzy logic proceeds in the representation of dispositions by the following steps:

1. A proposition is regarded as a collection of (usually implicit) fuzzy constraints.
2. An explanatory database contains lists of samples of the subject of the proposition together with the degree to which each predicate or constraint is fulfilled. These data are used to compute test scores of the degree to which each constraint is met. These test-scores then become the meaning of the fuzzy constraints.

Circumscription (McCarthy, 1980)

Circumscription is a form of non-monotonic reasoning (as distinct from non-monotonic logic) which reduces the context of a sentence to anything that is deducible from the sentence itself, and no more. Without such a mechanism, any statement may invoke all the knowledge the system possesses that is associated with whatever the topic of the statement is, much of which would probably be irrelevant. The question

“Crows and canaries are both birds; why is Tweetie afraid of crows?”

could give rise to consideration of the facts that ostriches and penguins are also birds and that ostriches don’t fly and put their heads in the sand while penguins swim and eat fish, all of which is irrelevant to the problem in hand. The purpose of circumscription is to limit evaluation of problem statements to the facts of the statement - what McCarthy describes as the ability to jump to conclusions.

Default Reasoning (Reiter, 1980)

Reiter’s Default Reasoning is based on the first order predicate calculus and attempts to solve a particular problem that arises in expressing commonsense knowledge in the classical formalism. The problem is that of drawing conclusions on the basis of incomplete knowledge when the missing information can be assumed, provided there is no evidence to the contrary. Such assumptions are possible because much real world knowledge about classes of objects is almost always true. Thus, most birds are capable of flight with a few exceptions such as penguins, ostriches, and kiwis, and provided they do not suffer from specific inabilities such as death or feet embedded in concrete.

Non-Monotonic Logic (McDermott & Doyle, 1980)

Non-monotonic logic attempts to formalize the representation of knowledge in such a way that the models maintained on the basis of the premises supplied can change, if necessary, as new premises are added. Thus, rather than determining the truth or falsity of statements as in classical logic, non-monotonic logics hold beliefs based on their current level of knowledge.

DISPOSITIONAL MODELS

Dispositional models attempt to establish the relationship between knowledge representation and memory. To paraphrase Schank (1981), understanding sentences involves adding information, generally commonsense, not explicit in the original sentence. Thus, a memory full of facts about the commonsense world is necessary in order to understand language. Furthermore, a model, or set of beliefs is necessary to provide expectations or explanations of an actor's behavior. Adding beliefs to a representation changes the idea of inference from simply adding information to permit parsing sentences to integrating data with a given memory model; this leads to the study of facts and beliefs in memory.

K-Lines (Minsky, 1981)

Minsky's major thesis is that the function of memory is to recreate a state of mind. Each memory must embody information that can later serve to reassemble the mechanisms that were active when the memory was formed.

Memory is posited to consist, at the highest level, of a number of loosely interconnected specialists - a "society of mind". Each of the specialists, in turn, comprises three lattices with connections between them.

The most basic lattice comprises "mental agents" or P-nodes. Some of these agents participate in any memorable event - an experience, an idea, or a problem solution - and become associated with that event. Reactivation of some of those agents recreates a "partial mental state" resembling the original.

Reactivation of P-nodes and consequent recreation of partial mental states is performed by K-Lines attached to nodes. The K-Lines originate in K-nodes embedded in a second lattice, the K-Pyramid. The

establishment of a K-Line between a K-node and some P-nodes occurs when a memorable mental event takes place. Information in the K-Pyramid flows downward, but not upward.

The third structure in Minsky's model is the N-Pyramid. Its function is to permit learning to take place, and it does so by constructing new K-nodes for P.

It may be useful to think of this structure as analogous to an ivory mandarin ball - spheres within spheres.

Memory Organization Packets: MOPS (Schank, 1981)

While Minsky presents a general theory of memory without reference to the representation of concepts, Schank's model is highly dependent on the inter-relationship of representations and memory. This is, perhaps, the result of the particular domain explored by Schank—temporal sequences of events.

The scripts, plans, goals, and themes of Schank's model are reminiscent of Minsky's P, K, and N pyramids, although including an additional level. An attempt to specify the relationship more precisely suggests the equivalence of scripts with the P-Pyramid, of plans with the K-Pyramid, and of goals with the N-Pyramid. The level of themes does not seem to be included in Minsky's model, although this may be a reflection of the "society of mind", with each theme representing a member of the society.

In addition to differentiating levels of description, Schank's model distinguishes four levels of memory by the degree of detail represented. These levels are:

1. Event Memory (EM) - specific remembrances of particular situations. After a while, the less salient aspects of an event fade away leaving generalized events plus the unusual or interesting parts of the original event.
2. Generalized Event Memory (GEM) - collocations of events whose common features have been abstracted. This is where general information is held about situations that have been experienced numerous times - e.g. dentists' waiting rooms.
3. Situational Memory (SM) - contains information about specific situations - e.g. going to medical practitioners' offices.
4. Intentional Memory (IM) - remembrances of generalizations at a higher level than SM - e.g.

getting a problem taken care of by an organization.

Scripts of particular situations do not exist as permanent memory structures but are reconstructed from more general, higher level structures, to aid in interpreting events as they unfold. The parts of scripts necessary for interpreting an event are retrieved from situational level memory structures referred to as Memory Organization Packets - MOPs. MOPs are collections of events that have become generalized ("mushed together" in Schank's words) and stored under them. MOPs are the means by which an appropriate episode in memory can be retrieved to aid in interpreting a specific event. Thus, connections must be established in memory from MOPs to the specific events that they are invoked to help process. These connections are evocative of Minsky's K-Lines.

A MOP aids in processing an event by virtue of the fact that it contains abstractions of similar previous events and, together with particularly memorable exceptions stored in EM, provides expectations about the development of events. Thus, a MOP is a high level script and is related to even higher-level MOPs. In Schank's example, a restaurant script is a lower level MOP with connections to more general MOPs such as social situations, contracts, and obtaining services. Like MOPs, scripts are subject to temporal precedence search, produce conceptual dependencies, and contain memories, so they may be thought of as sub-MOPs.

FUTURE TRENDS AND CONCLUSION

Although considerable effort has been spent on attempts to formalize commonsense knowledge representation, none of these has yet produced an entirely satisfactory result. Thus, there is still considerable room for work in this area

Furthermore, there has been little theoretical work on commonsense representation formalisms in recent years. The bulk of the efforts have shifted to projects utilizing various formalisms to implement commonsense knowledge bases. See "Commonsense Knowledge Representation II - Implementation" in this Encyclopedia.

KEY TERMS

Belief Maintenance Systems: Systems of logic that permit theorems to be updated as new knowledge becomes available.

Commonsense Knowledge: Knowledge of the basic facts and behaviors of the everyday world.

Dispositional Models: Representations of things or facts.

Logistic Models: Modified logics that attempt to overcome the problems of representing commonsense knowledge in the classic predicate calculus.

Monotonicity: A characteristic of logic that prevents changes to existing theorems, when new information becomes available.

Non-Monotonic Logic: A logic that attempts to overcome the restrictions of monotonicity.

Propositional Models: Descriptions of representations of things or concrete facts.

Representation Formalisms: Theoretical frameworks for representing commonsense knowledge.

ENDNOTE

- ¹ In this article, “commonsense” is written as one word, to distinguish such knowledge from the more usual “common sense” defined in the Oxford English Dictionary as “Good sound practical sense; combined tact and readiness in dealing with the every-day affairs of life; general sagacity.” Others use “commonsense” only as an adjective.

C

Commonsense Knowledge Representation II

Phillip Ein-Dor

Tel-Aviv University, Israel

INTRODUCTION

Early attempts to implement systems that understand commonsense knowledge did so for very restricted domains. For example, the Planes system [Waltz, 1978] knew real world facts about a fleet of airplanes and could answer questions about them put to it in English. It had, however, no behaviors, could not interpret the facts, draw inferences from them or solve problems, other than those that have to do with understanding the questions. At the other extreme, SHRDLU (Winograd, 1973) understood situations in its domain of discourse (which it perceived visually), accepted commands in natural language to perform behaviors in that domain and solved problems arising in execution of the commands; all these capabilities were restricted, however, to SHRDLU's artificial world of colored toy blocks. Thus, in implemented systems it appears that there may be a trade off between the degree of realism of the domain and the number of capabilities that can be implemented.

In the frames versus logic debate (see Commonsense Knowledge Representation I - Formalisms in this Encyclopedia), the real problem, in Israel's (1983) opinion, is not the representation formalism itself, but rather that the facts of the commonsense world have not been formulated, and this is more critical than choice of a particular formalism. A notable attempt to formulate the "facts of the commonsense world" is that of Hayes [1978a, 1978b, 1979] under the heading of **naïve physics**. This work employs **first-order predicate calculus** to represent commonsense knowledge of the everyday physical world. The author of this survey has undertaken a similar effort with respect to **commonsense business knowledge** (Ein-Dor and Ginzberg 1989). Some broader attempts to formulate commonsense knowledge bases are cited in the section Commonsense Knowledge Bases.

COMMONSENSE AND EXPERT SYSTEMS

The perception that **expert systems** are not currently sufficient for **commonsense representation** is strengthened by the conscious avoidance in that field of commonsense problems. An excellent example is the following maxim for expert system construction:

Focus on a narrow specialty area that does not involve a lot of commonsense knowledge. ... to build a system with expertise in several domains is extremely difficult, since this is likely to involve different paradigms and formalisms. (Buchanan et al., 1983)

In this sense, much of the practical work on expert systems has deviated from the tradition in Artificial Intelligence research of striving for **generality**, an effort well exemplified by the General Problem Solver (Ernst and Newell, 1969) and by work in **natural language processing**. Common sense research, on the other hand, seems to fit squarely into the AI tradition for, to the attributes of common sense (Commonsense Knowledge Representation I), it is necessary to add one more implicit attribute, namely the ability to apply any commonsense knowledge in ANY relevant domain. This need for generality appears to be one of the greatest difficulties in representing common sense.

Consider, for example, commonsense information about measurement; knowledge of appropriate measures, conversions between them, and the duration of their applicability are necessary in fields as diverse as medicine, business, and physics. However, each expert system represents knowledge, including the necessary knowledge about measuring scales, in the manner most convenient for its specific purposes. No such representation is likely to be very useful in any other system in the same domain, and certainly not for systems in other domains. Thus, it appears that the reason for the inability of expert systems as currently developed to

represent general purpose common sense is primarily a function of the **generality** of commonsense versus the **specificity** of expert systems.

From a positive point of view, one of the major aims of commonsense systems must be to represent knowledge in such a way that it can be useful in any domain; i.e. when storage strategies cannot be based on prior information about the uses to which the knowledge will be put.

This, then, is the major difference between expert systems and commonsense systems; while the former deal mainly with the particular knowledge and behaviors of a strictly bounded activity, common sense must deal with all areas of knowledge and behavior not specifically claimed by a body of experts. An expert system that knows about internal medicine does not know about skin diseases or toxicology and certainly not about drilling rigs or coal mining. Common sense systems, on the other hand, should know about colds and headaches and cars and the weather and supermarkets and restaurants and “chalk and cheese and sealing wax and cabbages and kings” (Carroll, 1872).

COMMONSENSE KNOWLEDGE BASE IMPLEMENTATIONS

Given the importance of commonsense knowledge, and because such knowledge is necessary for a wide range of applications, a number of efforts have been made to construct universally applicable commonsense knowledge bases. Three of the most prominent are Cyc, ConceptNet, and WordNet.

Cyc

The **Cyc** project (Lenat et al. 1990; Lenat, 2006) was initiated in 1984 by **Douglas Lenat** who has been at its head ever since. The objective of the project was to build a knowledge base of all the commonsense knowledge necessary to understand the set of articles in an encyclopedia. As of 2005, the **knowledge base** contained about 15,000 predicates, 300,000 concepts, and 3,200,000 assertions – facts, rules of thumb and heuristics for reasoning about everyday objects and events. The project is still active and the knowledge base continues to grow.

The formalism employed in Cyc is the **predicate calculus** and assertions are entered manually. (Cycorp,

2007). OpenCyc, a freely available version of Cyc may be downloaded from <http://www.opencyc.org/>.

ConceptNet

ConceptNet (Liu and Singh, 2004) is a commonsense knowledge base and natural-language-processing toolkit that supports many practical textual-reasoning tasks. Rather than assertions being registered manually as in Cyc, in ConceptNet they are generated automatically from 700,000 sentences of the **Open Mind Common Sense Project** (Singh, 2002) provided by over 14,000 authors. There is a concise version with 200,000 assertions and a full version of 1.6 million assertions.

ConceptNet is constructed as a **semantic net**.

A freely available version of the system may be downloaded at <http://web.media.mit.edu/~hugo/conceptnet/#download>.

WordNet

WordNet (Felbaum, 1998) is described as follows (WordNet, 2007): “Nouns, verbs, adjectives and adverbs are grouped into sets of cognitive synonyms (**synsets**), each expressing a distinct concept. Synsets are interlinked by means of conceptual-semantic and lexical relations. The resulting network of meaningfully related words and concepts can be navigated with the browser. ... WordNet’s structure makes it a useful tool for computational linguistics and natural language processing.”

WordNet contains about 155,000 words, 118,000 synsets, and 207,000 word-sense pairs.

WordNet is available for free download at <http://wordnet.princeton.edu/obtain>.

FUTURE TRENDS AND CONCLUSION

Any system designed to process natural language must contain commonsense knowledge as do many other types of systems. Thus, the development of commonsense knowledge bases is sure to continue.

As a complete commonsense knowledge base must contain very large quantities of knowledge, the development of such a base is a very lengthy process that must be cumulative if it is to achieve its goal. Thus, commonsense knowledge base implementations will expand and improve over a lengthy period of time.

KEY TERMS

Commonsense Knowledge: Knowledge of the basic facts of the everyday world; the knowledge that any participant in a culture expects any other participant in that culture to possess.

Commonsense Knowledge Base: A knowledge base containing commonsense knowledge and mechanisms for drawing inferences or processing natural language on the basis of that knowledge.

ConceptNet: A commonsense knowledge base implementation structured as a semantic net.

Cyc: A large commonsense knowledge base implementation utilizing predicate calculus as the representation mechanism.

Expert Knowledge: Knowledge possessed by experts in a particular domain. Systems representing expert knowledge are generally rule-based.

Implementation: The construction of a computerized system to represent and manipulate commonsense knowledge.

WordNet: A commonsense knowledge base implementation based on a semantic net structure.

A Comparative Study on E-Note-Taking

Shaista Rashid

University of Bradford, UK

Dimitris Rigas

University of Bradford, UK

INTRODUCTION

In all walks of life individuals are involved in a cumulative and incremental process of knowledge acquisition. This involves the accessing, processing and understanding of information which can be gained through many different forms. These include, deliberate means by picking up a book or passive by listening to someone. The content of knowledge is translated by individuals and often recorded by the skill of note-taking, which differs in method from one person to another. This article presents an investigation into the techniques to take notes including the most popular Cornell method. A comparative analysis with the Outlining and Mapping methods are carried out stating strengths and weaknesses of each in terms of simplicity, usefulness and effectiveness. The processes of developing such skills are not easy or straightforward and performance is much influenced by cognition. Therefore, such associations regarding cognitive conceptions involve the exploration into note-taking processes encoding and storage, attention and concentration, memory and other stimuli factors such as multimedia.

The social changes within education from the traditional manner of study to electronic are being adapted by institutes. This change varies from computerising a sub-component of learning to simulating an entire lecture environment. This has enabled students to explore academia more conveniently however, is still arguable about its feasibility. The article discusses the underlying pedagogical principles, deriving instructions for the development of an e-learning environment. Furthermore, embarking on Tablet PC's to replace the blackboard in combination with annotation applications is investigated. Semantic analysis into the paradigm shift in e-learning and knowledge management replacing classroom interaction presents its potential in the learning domain. The article concludes with ideas for the design and development of an electronic note-taking platform.

BACKGROUND

Over the years, research into note-taking has been carried out intensively. The paper aims to comparatively analyse the various note-taking techniques, providing an explanation into the effectiveness and simplicity. The relationship between cognition and note-taking is studied presenting a breakdown into the processes involved. Due to the vast amount of research into cognition its relevance is imperative. Although, great research within both areas has been undertaken to design an electronic note-taking tool, an analysis into existing applications has also been conducted, with Microsoft OneNote being the most favourable. This is an annotation application that has no predefined technique to record notes or annotations and saves handwriting as an image. Throughout the literature many authors work contributing to this study will be presented.

COMPARATIVE STUDY

This article presents an insight into note-taking, the various methods, cognitive psychology and the paradigm shift from traditional manner of study to electronic.

Note-Taking Techniques

Theoretically, note-taking is perceived as the transfer of information from one mind to the other. Today, the most popular note-taking technique is the Cornell note-taking method, also referred to as 'Do-it-right-in-the-first-place'. This note-taking method was developed over 40 years ago by Professor Walter Pauk at the Cornell University (Pauk & Owens, 2005). The main purpose of developing this method was to assist students to organise their notes in a meaningful manner. This technique involves a systematic approach for arranging and condensing notes without the need to do multiple recopying. The method is simple and

effective specifying three areas only. Area A keywords, Area B notes-taking and Area C summary.

Area A is assigned to keywords or phrases, which are formed by students towards the end of the lecture. Over the years an alternative has been questions aiding recall over recognition. These cues are known to assist memory and pose as a reminder alongside helping to identify relationships, also referred as the Q-System (Pauk & Owens, 2005). Area B remains for the recording of notes during lecture. Here the student attempts to capture as much information as possible. Finally, Area C is left for the student to summarise the notes and reflect upon the main ideas of the lecture (Pauk & Owens, 2005).

The main advantage of this technique is its clear-cut and organised structure. This technique is also suitable for technical modules including Mathematics and Physics and non-technical modules such as English and History. During an engineering and applied sciences

workshop, experiments involving 70 student participants revealed this note-taking method is straightforward (Anderson-Rowland, Aroz, Blaisdell, Cosgrove, Fussell, McCartney & Reyes, 1996). The authors Anderson-Rowland *et al.* (1996), state this method enables the organisation of notes, entails interaction and concentration therefore; a scheduled review can be conducted immediately highlighting keywords. Moreover, as the students can summarise content this facilitates learning by increasing understanding. Additionally, the strength of the technique is the ability to take notes instantaneously, saving time and effort due to its systematic structure.

In comparison, the Outlining method (see Figure 2) has a more spatial and meaningful layout, implicitly encoding conceptual relations. For example, indentation may imply grouping and proximity conceptual closeness (Ward & Tatsukawa, 2003).

The method consists of dashes or indentation and is not suitable for technical modules such as Mathematics or Physics. This technique requires indentation with spaces towards the right for specific facts. Relationships are represented through indentation. Note-takers are required to specify points in an organised format arranging a pattern and sequence built by space indentation. Important points are separated and kept furthest to the left, bringing in more specific points towards the right. Distance from the major point indicates the level of importance. The main advantage of this technique is the neatly organised structure allowing reviewing to be conducted without any difficulty. However, the Outlining method requires the student's full concentration to achieve maximum organisation of notes. Consequently, the technique is not appropriate if the lecturer is going at a fast pace. The method has also been disapproved by Fox (1959) because of its confusing organisational structure. This is mainly due to the arrangement of numerals, capitalised letters and so forth.

In contrast to the Cornell and Outlining methods, the Mapping method (see Figure 3) is a graphical representation of the lecture content. Students are stimulated to visually determine links illustrating relationships between facts and concepts. Concept maps enable brainstorming, breakdown and representation of complex scenarios, identifying and providing solutions for flaws and summarising information. To enhance accuracy students must actively participate and initiate critical thinking. However, a drawback arguably, has been the structural organisation and relationship of

Figure 1. The Cornell note-taking method (adapted from Pauk & Owens, 2005)

nodes especially, questioning the hierarchical structure (Hibberd, Jones, & Morris, 2002). Alternative structures have been discussed including chain, spider maps and networks (Derbentseva & Safayeni, 2004).

E-Learning

E-learning, also known as distance education employs numerous technological devices. Today, educational institutes are well-known to deliver academia over the Internet. The growth of the internet is ever-increasing with great potential for not only learning material but also as a collaborative learning environment. The major difference between traditional learning and electronic learning is the mode of instruction by which information is communicated.

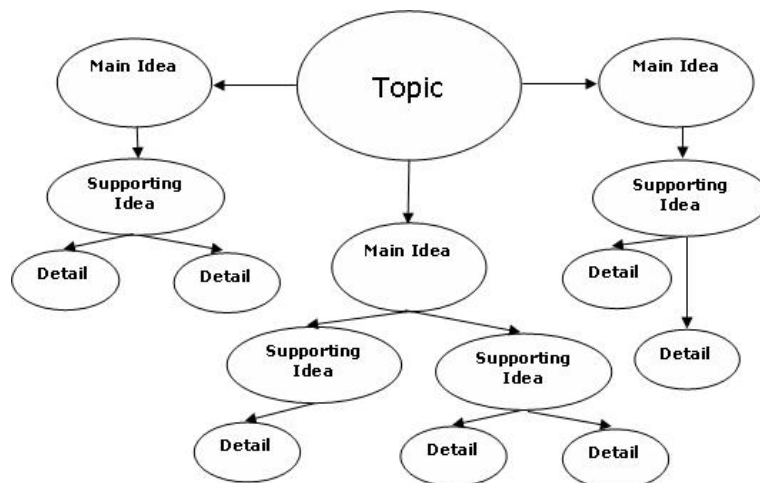

To have a successful e-learning system all sub-components and interrelated processes must be considered, because if one process fails then the entire system fails. Therefore, it is necessary to derive a series of pedagogical principles. Underlying pedagogical principles include considering the user's behaviour towards the system, as it is an isolated activity resulting in user's becoming frustrated. As the internet has a great deal of knowledge it can be presented in a bias manner providing users with partial information. Considerations for the environment and the user actions to be performed to achieve a specific goal must be outlined. Moreover, user's interpersonal skills including their attitudes, perceptions and behaviour are central to influencing the effectiveness of the system. It has been learned

e-learning reduces teaching time, increase proficiency and improves retention. However, this is not always correct, as in one study, results of online lecture notes showed students performed weaker (Barnett, 2003). From student's perspective, they continuously pursue communication and support to influence their learning. They also welcome constructive feedback (Mason, 2001).

The major challenges faced by the e-learning society are the culture clash and lack of motivation towards an electronic learning environment. People are just not prepared to accept the change. A major factor determining successful outcomes of such systems is the level of interactivity provided. Other significant pedagogical principles include the level of control users feel, in comparison to traditional manner of learning where the lecturer has full control over the lecture environment. Moreover, the development of a suitable interface is necessary considering usability factors such as efficiency, error rates, memoryability, learnability and subject satisfaction. As a tutor, the planning behind the course structure is important, paying close attention towards the structure of content. Tutors must ensure students receive feedback in an appropriate time maintaining time management. Overall, before considering the design and development of an e-learning environment the main factors to consider include the learners, content, technology, teaching techniques, and so forth (Hamid, 2002).

Technologies associated with e-learning have increased usage of bandwidth and internet access. Presently, there are two key technologies used to de-

Figure 3. Example of the mapping method

liver e-learning, 'scheduled delivery platforms' and 'on-demand delivery platforms'. Scheduled delivery platforms include multicasts, virtual libraries and remote laboratories, yet the constraints of these include time and area restraints. To further improve these systems, on-demand delivery platforms provide 24 hour support maintaining flexibility of learning (Hamilton, Richards & Sharp, 2001).

The efficacy of electronic notes in one particular study showed improvement in students understanding of lecture content, resulting in an overwhelming 96% users feeling e-notes are an effective tool (Wirth, 2003). Users are able to annotate, collaborate and discuss subject content. This increases learning efficiency by allowing the user to engage into the text, improving their comprehension and supporting memorisation. Recall of specific details is also enhanced (Wolfe, 2000). Numerous annotation applications have been introduced including Microsoft Word and OneNote primarily concerned with annotation. SharePoint™ allows manipulation editing and annotation simultaneously as well as Re:Mark™. Microsoft OneNote as an annotation tool is more popular however, the end-user is required to possess a copy of it in order to use it, unlike Microsoft Journal which can be exported as a .mhtml file (Cicchino, 2003). Additionally, handwriting is translated as an image rather than text that can be explored (McCall, 2005). The benefits include ability to record a lecture and annotate, referencing to specific points within the recording. These can then be used later (McCall, 2005).

Tablet PC's are being used to replace the blackboard presenting course material through a data projector. Many academic institutes are adopting these as a teaching tool (Clark, 2004) or are providing students with them as teaching devices (Lowe, 2004). The major strength of a Tablet PC is its interactivity between face-to-face instructions (Cicchino, 2003). However, a study that provided students with pen-based computers for the purpose of taking notes presented the project as unsuccessful because the devices were unsuitable in terms of performance, poor resolution, and network factors (Truong, Abowd & Brotherton, 1999).

Cognition

The most common mode of instruction in higher education is lectures where attending students take notes based on the lecture content (Tran & Lawson, 2001). In

class, students spend approximately 80% of their time listening to the lecture (Armbruster, 2000) and the reason students take notes is because of their usefulness towards learning and due to social pressures (Tran & Lawson, 2001). Students vary their note-taking technique according to personal experience, existing knowledge, and appropriateness to the lecture format. Problems within the classroom are caused due to student's inability to copy information presented by the lecturer (Komagata, Ohira, Kurakawa & Nakakoji, 2001). Whilst engaging in reading or listening metacognition, the human mind has a tendency to wander off thinking about thoughts other than what is being taught or learnt.

During the learning process, effects on learning occur during the encoding and storage processes. The encoding stage is when students attend lecture and record lecture notes whereas, the storage phase is when students review their notes. To achieve optimum performance, both the encoding and storage processes should be combined. The reviewing of lecture notes is significantly important especially when conducted in close proximity to an exam. Additionally, students should also monitor their individual progress and understanding of information before an exam. This can be achieved by carrying out self-testing. This method can also be encouraged by the lecturer providing relevant material for example, past exam papers.

Students with greater memory-ability benefit from note-taking with studies finding students with lower memory-ability record a lower number of words and complete ideas (Kiewra & Benton, 1988). This is due to variations within the working memory as information is stored and manipulated there. Therefore, the ability of note-takers to pick out relevant details, maintain knowledge and combine new knowledge to existing knowledge are essential factors. Human memory can be broken down into three types; Short-term; long-term and sensory memory. Short-term memory allows information to be stored for a short period before being forgotten or transferred to long-term memory. Long-term memory endures information for a longer period into the memory circuit. The brain circuit includes the cerebral cortex and hippocampus. Finally, the sensory memory is the initial storage of information lasting an instant, consisting of visual and auditory memories. Information here is typically gathered through the sight and sound senses.

The incorporation of multimedia within education can enhance the learning experience in a number of

ways. Significant sensory aids can be provided, interactivity can be increased and a richer learning experience can be initiated. The presentation of learning material and the manner in which content is captured is important. This is because if during a lecture organisational cues are explicitly defined the organisational process is guided (Titsworth & Kiewra, 2004). Moreover, the use of non-speech audio amalgamated within user-interfaces is becoming increasingly popular. If complimented with visual output it can increase the amount of information communicated to the user. A typical student captures 29% visual, 34% auditory and 37% haptic metaphors (Dryden & Vos, 1999). Sound provides greater flexibility as it can be heard 360° without having to concentrate; this is in comparison to visual output where the retina subtends an angle of 2° around the point of fixation. Consequently sound is a superb way of capturing user attention. Furthermore, graphical displays including icons, menu graphics and so forth can be used as an iconic representation of a user's action.

FUTURE TRENDS

The increase in electronic learning tools and e-learning environments within education are ever-increasing and so the necessity to derive a flexible learning structure with interactivity is paramount. Studies relating to the computerisation of note-taking tools are not so prominent. Nonetheless, the comparative study does demonstrate the effectiveness of using a note-taking method, especially the Cornell method which is most popular. Additionally, a popularity trend amongst multi-modality including audio sounds in particular earcons have shown, there is potential to combine these within learning to benefit from the experience and enhance interactivity. Moreover, in-depth research into psychological learning parameters especially encoding and storage processes have demonstrated the need to combine the two together to optimise performance. The introduction of annotation applications has instigated a trend towards electronic learning platforms although, usability issues to personalise the student experience must be further studied.

CONCLUSION

This article provides a comparative study into note-taking techniques, the processes involved and the effects of cognition upon learning. The literature suggests current electronic learning tools amalgamate many learning functions, including lecture notes, handouts, discussions and so forth into one application. Integration issues including cost factors, hardware deficiencies and malfunctions in subcomponents leading to system failures are major issues brought to light. Moreover, the primary focus into the skill and technique of note-taking have been analysed with no such technique provided as an electronic tool. Therefore, the design and development of a sub-component of e-learning, a note-taking tool is being considered based upon the studied research. The Cornell note-taking method has been arguably more effective with regards to simplicity, ability to deploy it within any subject area and appropriateness. Therefore future work will consider the influences of multimedia upon this technique, including earcons, visual structure, layout, and possibly the incorporation of speech.

KEY TERMS

Annotation: The activity of briefly describing or explaining information. It can also involve summarising or evaluating content.

Cognitive Psychology: A study into cognition such as mental processes describing human behaviour, understanding perceptions, examining memory, attention span, concentration, and forgetfulness. The purpose of understanding humans and the way they mentally function.

Information Processing: The ability to capture, store and manipulate information. This consists of two main processes; encoding and storage. Students record notes during the encoding stage and conduct reviewing thereafter, in the storage phase.

Metacognition: The ability and skills of learners to be aware of and monitor their learning processes.

Multimodality: An electronic system that enhances interactivity by amalgamating audio, visual and speech metaphors.

Pedagogical Principles: Key issues to instruct the design and development of an electronic learning environment.

Platform: Computer framework allowing software to run for a specific purpose.

Traditional Manner of Study: Typically a classroom environment with the tutor writing content on a blackboard and students using pen and paper to record the content as their own notes. The tutor dominates the classroom environment unlike in electronic learning where, the user has a sense of control due to flexibility in learning.

A Comparison of Cooling Schedules for Simulated Annealing

José Fernando Díaz Martín
University of Deusto, Spain

Jesús M. Riaño Sierra
University of Deusto, Spain

INTRODUCTION

Simulated annealing is one of the most important **metaheuristics** or general-purpose algorithms of **combinatorial optimization**, whose properties of convergence towards high quality solutions are well known, although with a high computational cost. Due to that, it has been produced a quite number of research works on the convergence speed of the algorithm, especially on the treatment of the temperature parameter, which is known as **cooling schedule** or strategy. In this article we make a comparative study of the performance of simulated annealing using the most important cooling strategies (Kirkpatrick, S., Gelatt, C.D. & Vecchi, M.P., 1983), (Dowsland, K.A., 2001), (Luke, B.T., 1995), (Locatelli, M., 2000). Two classical problems of combinatorial optimization are used in the practical analysis of the algorithm: the **travelling salesman problem** and the **quadratic assignment problem**.

BACKGROUND

The main aim of **combinatorial optimization** is the analysis and the algorithmic solving of constrained optimization problems with discrete variables. Problems that require algorithms of non-polynomial time complexity with respect to the problem size, called NP-complete problems, are the most important ones.

The general solving techniques of this type of problems belong to three different, but related, research fields. First, we can mention heuristic search algorithms, such as the deterministic algorithms of **local search** (Johnson, D.S., Papadimitriou, C.H. & Yannakakis, M., 1985), (Aarts, E.H.L. & Lenstra, J., 1997), the stochastic algorithm of **simulated annealing** (Kirkpatrick, S., Gelatt, C.D. & Vecchi, M.P., 1983), and the **taboo search** (Glover, F., 1986). A second

kind of solving techniques are algorithms inspired in genetics and the evolution theory, such as *genetic and evolutionary algorithms* (Holland, J.H., 1973), (Goldberg, D.E., 1989), and *memetic algorithms* (Moscato, P., 1999). Finally, due to the collective computation properties of some neural models, the area of artificial neural networks has contributed a third approach, although possibly not so relevant as the former ones, to the combinatorial optimization problem solving with the *Hopfield nets* (Hopfield, J.J. & Tank, D., 1985), the *Boltzmann machine* (Aarts, E.H.L. & Korst, J., 1989), and the *self-organizing map* (Kohonen, T., 1988).

Simulated Annealing Algorithm

The **simulated annealing** is a stochastic variant of the **local search** that incorporates a stochastic criterion of acceptance of worse quality solutions, in order to prevent the algorithm from being prematurely trapped in local optima. This acceptance criterion is based on the **Metropolis algorithm** for simulation of physical systems subject to a heat source (Metropolis, N., Rosenbluth, A., Rosenbluth, M., Teller, A. & Teller, E., 1953).

Algorithm (simulated annealing). Be a combinatorial optimization problem (X, S, f, R) , with generator function of random k -neighbour feasible solutions $g : S \times [0, 1] \rightarrow S$. Supposing, without loss of generality, that f must be minimized, the **simulated annealing** algorithm can be described in the following way:

1. Set an initial random feasible solution as current solution, $s_1 = s_0$.
2. Set initial temperature or control parameter $T = T_0$.
3. Obtain a new solution that differs from the current one in the value of k variables using the generator

A Comparison of Cooling Schedules

- function of random k -neighbour feasible solutions, $s_j = g(s_i, \text{random}[0,1])$.
4. If the new solution s_j is better than the current one, $f(s_j) < f(s_i)$, then s_j is set as current solution, $s_i = s_j$. Otherwise, if

$$e^{\frac{f(s_i) - f(s_j)}{T}} > \text{random}[0,1]$$

5. s_j is equally accepted as current solution, $s_i = s_j$.
5. If the number of executed state transitions (steps 3 and 4) for the current value of temperature is equal to L , then the temperature T is decreased.
6. If there are some k -neighbour feasible solutions near to the current one that have not been processed yet, steps 3 to 5 must be repeated. The algorithm ends in case the set of k -neighbour solutions near to the current one has been processed completely with a probability close to 1 without obtaining any improvement in the quality of the solutions.

The most important feature of the simulated annealing algorithm is that, besides accepting transitions that imply an improvement in the solution cost, it also allows to accept a decreasing number of transitions that mean a quality loss of the solution.

The simulated annealing algorithm converges asymptotically towards the set of global optimal solutions of the problem. E. Aarts and J. Korst provide a complete proof in their book *Simulated Annealing and Boltzmann Machines: A Stochastic Approach to Combinatorial Optimization and Neural Computing* (1989). Essentially, the convergence condition towards global optimum sets that temperature T of the system must be decreased logarithmically according to the equation:

$$T_k = \frac{T_0}{1 + \text{Log}(1 + k)} \quad (1)$$

where $k = 0, 1, \dots, n$ indicates the temperature cycle. However, this function of system cooling requires a prohibitive computing time, so it is necessary to consider faster methods of temperature decrease.

Cooling Schedules

A practical simulated annealing implementation requires generating a finite sequence of decreasing

values of temperature T , and a finite number L of state transitions for each temperature value. To achieve this aim, a **cooling schedule** must be specified.

The following cooling schedule, frequently used in the literature, was proposed by Kirkpatrick, Gelatt and Vecchi (1983), and it consists of three parameters:

- **Initial temperature, T_0 .** The initial value of temperature must be high enough so that any new solution generated in a state transition should be accepted with a certain probability close to 1.
- **Temperature decrease function.** Generally, an exponential decrease function is used, such as $T_k = T_0 \cdot \alpha^k$, where α is a constant smaller than the unit. Usual values of α fluctuate between 0.8 and 0.99.
- **Number of state transitions, L ,** for each temperature value. Intuitively, the number of transitions for each temperature must be high enough so that, if no solution changes were accepted, the whole set of k -neighbour feasible solutions near to the current one could be gone round with a probability close to 1.

The initial temperature, T_0 , and the number of state transitions, L , can be easily obtained. On the other hand, the temperature decrease function has been studied in numerous research works (Laarhoven, P.J.M. Van & Aarts, E.H.L., 1987), (Dowsland, K.A., 2001), (Luke, B.T., 2005), (Locatelli, M., 2000).

MAIN FOCUS OF THE CHAPTER

In this section nine different cooling schedules used in the comparison of the simulated annealing algorithm are described. They all consist of, at least, three parameters: initial temperature T_0 , temperature decrease function, and number of state transitions L for each temperature.

Multiplicative Monotonic Cooling

In the multiplicative monotonic cooling, the system temperature T at cycle k is computed multiplying the initial temperature T_0 by a factor that decreases with respect to cycle k . Four variants are considered:

- *Exponential multiplicative cooling* (Figure 1-A), proposed by Kirkpatrick, Gelatt and Vecchi (1983), and used as reference in the comparison among the different cooling criteria. The temperature decrease is made multiplying the initial temperature T_0 by a factor that decreases exponentially with respect to temperature cycle k :

$$T_k = T_0 \cdot \alpha^k \quad (0.8 \leq \alpha \leq 0.9) \quad (2)$$

- *Logarithmical multiplicative cooling* (figure 1-B), based on the asymptotical convergence condition of simulated annealing (Aarts, E.H.L. & Korst, J., 1989), but incorporating a factor α of cooling speeding-up that makes possible its use in practice. The temperature decrease is made multiplying the initial temperature T_0 by a factor that decreases in inverse proportion to the natural logarithm of temperature cycle k :

$$T_k = \frac{T_0}{1 + \alpha \text{Log}(1 + k)} \quad (\alpha > 1) \quad (3)$$

- *Linear multiplicative cooling* (Figure 1-C). The temperature decrease is made multiplying the initial temperature T_0 by a factor that decreases in inverse proportion to the temperature cycle k :

$$T_k = \frac{T_0}{1 + \alpha k} \quad (\alpha > 0) \quad (4)$$

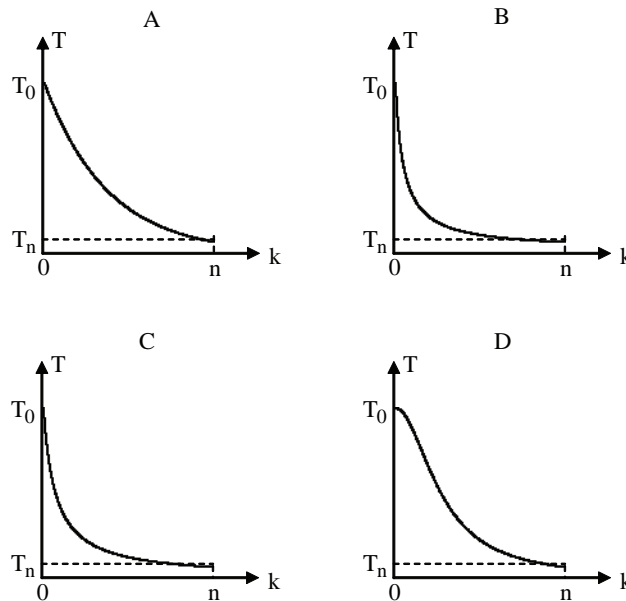

- *Quadratic multiplicative cooling* (Figure 1-D). The temperature decrease is made multiplying the initial temperature T_0 by a factor that decreases in inverse proportion to the square of temperature cycle k :

$$T_k = \frac{T_0}{1 + \alpha k^2} \quad (\alpha > 0) \quad (5)$$

Additive Monotonic Cooling

In the additive monotonic cooling, we must take into account two additional parameters: the number n of cooling cycles, and the final temperature T_n of the system. In this type of cooling, the system temperature T at cycle k is computed adding to the final temperature

Figure 1. Multiplicative cooling curves: (A) Exponential, (B) logarithmical, (C) linear, (D) quadratic

A Comparison of Cooling Schedules

T_n a term that decreases with respect to cycle k . Four variants based on the formulae proposed by B. T. Luke (2005) are considered:

- *Linear additive cooling* (Figure 2-A). The temperature decrease is computed adding to the final temperature T_n a term that decreases linearly with respect to temperature cycle k :

$$T_k = T_n + (T_0 - T_n) \left(\frac{n-k}{n} \right) \quad (6)$$

- *Quadratic additive cooling* (Figure 2-B). The temperature decrease is computed adding to the final temperature T_n a term that decreases in proportion to the square of temperature cycle k :

$$T_k = T_n + (T_0 - T_n) \left(\frac{n-k}{n} \right)^2 \quad (7)$$

- *Exponential additive cooling* (Figure 2-C). The temperature decrease is computed adding to the

final temperature T_n a term that decreases in inverse proportion to the e number raised to the power of temperature cycle k :

$$T_k = T_n + (T_0 - T_n) \left(\frac{1}{1 + e^{\frac{2 \ln(T_0 - T_n)}{n} (k - \frac{1}{2}n)}} \right) \quad (8)$$

- *Trigonometric additive cooling* (Figure 2-D). The temperature decrease is computed adding to the final temperature T_n a term that decreases in proportion to the cosine of temperature cycle k :

$$T_k = T_n + \frac{1}{2} (T_0 - T_n) \left(1 + \cos \left(\frac{k\pi}{n} \right) \right) \quad (9)$$

Non-Monotonic Adaptive Cooling

In the non-monotonic adaptive cooling, the system temperature T at each state transition is computed multiplying the temperature value T_k , obtained by any of the former criteria, by an adaptive factor μ based on the difference between the current solution objective,

Figure 2: Additive cooling curves: (A) linear, (B) quadratic, (C) exponential, (D) trigonometric.

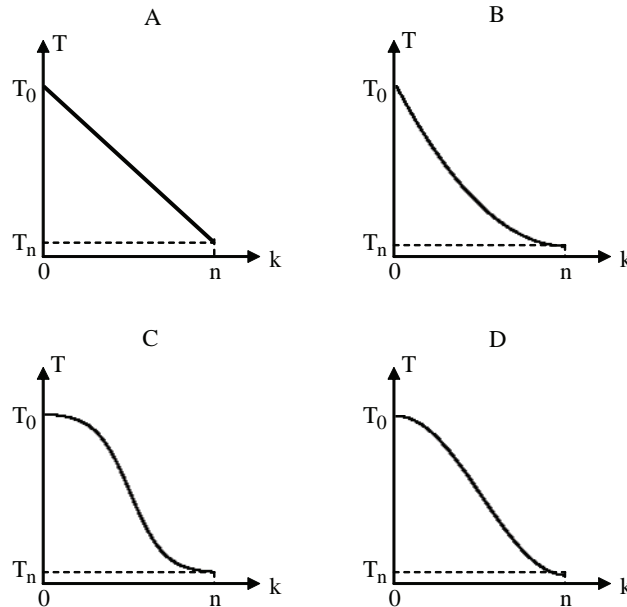

Figure 3. Curve of non-monotonic adaptive cooling

$f(s_i)$, and the best objective achieved until that moment by the algorithm, noted f^* :

$$T = \mu T_k = \left(1 + \frac{f(s_i) - f^*}{f(s_i)} \right) T_k \quad (10)$$

Note that the inequality $1 \leq \mu < 2$ is verified. This factor μ means that the greater the distance between current solution and best achieved solution is, the greater the temperature is, and consequently the allowed energy hops. This criterion is a variant of the one proposed by M. Locatelli (2000), and it can be used in combination with any of the former criteria to compute T_k . In the comparison, the standard exponential multiplicative cooling has been used for this purpose. So the cooling curve is characterized by a fluctuant random behaviour comprised between the exponential curve defined by T_k and its double value $2T_k$ (Figure 3).

Combinatorial Optimization Problems Used in the Comparison

Travelling Salesman Problem. The Travelling Salesman Problem, TSP, consists of finding the shortest cyclic path to travel round n cities so that each city is visited only once. The objective function f to minimize is given by the expression:

$$f(s) = \sum_{i=1}^n d(x_i, x_{(i \bmod n)+1}),$$

where each variable x_i means the city that is visited at position i of the tour, and $d(x_i, x_j)$ is the distance between the cities x_i and x_j . The tests have been made using two

different instances of the euclidean TSP. The first one obtains a tour of 47 European cities and the second one a tour of 80 cities.

Quadratic Assignment Problem. The Quadratic Assignment Problem, QAP, consists of finding the optimal location of n workshops in p available places ($p \geq n$), considering that between each two shops a specific amount of goods must be transported with a cost per unit that is different depending on where the shops are. The objective is minimizing the total cost of goods transport among the workshops. The objective function f to minimize is given by the expression:

$$f(s) = \sum_{i=1}^{n-1} \sum_{j=i+1}^n c(x_i, x_j) q(i, j),$$

where each variable x_i means the place in which workshop i is located, $c(x_i, x_j)$ is the cost per unit of goods transport between the places where shops i and j are, and $q(i, j)$ is the amount of goods that must be transported between these shops. The tests have been made using two different instances of the QAP: The first one with 47 workshops to be located in 47 European cities, and the second one with 80 workshops to be located in 80 cities.

Selection of parameters

For each problem instance, all variants of the algorithm use the same values of initial temperature T_0 and number L of state transitions for each temperature. The initial temperature T_0 must be high enough to accept any state transition to a worse solution. The number L of state transitions must guarantee with a probability η close to 1 that, if no solution changes are accepted, any k -neighbour solution near to the current one could be process.

In order to determine the other temperature decrease parameters of each cooling schedule under similar conditions of execution time, we consider the mean final temperature \bar{T} and the temperature standard error σ of the exponential multiplicative cooling of Kirkpatrick, Gelatt and Vecchi with decreasing factor $\alpha = 0.95$. The objective is to determine the temperature decrease parameters in such a way that a temperature in the interval $[\bar{T} - \sigma, \bar{T} + \sigma]$ is reached in the same number of cycles as the exponential multiplicative cooling. We distinguish three cases:

- *Multiplicative monotonic cooling.* The decrease factor α that appears in the temperature decrease equations must allow to reach the temperature $\bar{T} + \sigma$, or highest temperature from which the end of the algorithm is very probable, in the same number n of cycles as the exponential multiplicative cooling. Knowing that for this cooling the number n of cycles is:

$$\bar{T} + \sigma = T_0 \cdot (0.95)^n \Rightarrow n = \frac{\text{Log}\left(\frac{\bar{T} + \sigma}{T_0}\right)}{\text{Log}(0.95)} \quad (11)$$

it results for the logarithmic multiplicative cooling:

$$\bar{T} + \sigma = \frac{T_0}{1 + \alpha \text{Log}(1 + n)} \Rightarrow \alpha = \frac{\frac{T_0}{\bar{T} + \sigma} - 1}{\text{Log}(1 + n)} \quad (12)$$

for the linear multiplicative cooling:

$$\bar{T} + \sigma = \frac{T_0}{1 + \alpha n} \Rightarrow \alpha = \frac{\frac{T_0}{\bar{T} + \sigma} - 1}{n} \quad (13)$$

and for the quadratic multiplicative cooling:

$$\bar{T} + \sigma = \frac{T_0}{1 + \alpha n^2} \Rightarrow \alpha = \frac{\frac{T_0}{\bar{T} + \sigma} - 1}{n^2} \quad (14)$$

- *Additive monotonic cooling.* Final temperature is $T_n = \bar{T} - \sigma$, and number n of temperature cycles is equal to the corresponding number of cycles of the exponential multiplicative cooling for that final temperature, that is:

$$\bar{T} - \sigma = T_0 \cdot (0.95)^n \Rightarrow n = \frac{\text{Log}\left(\frac{\bar{T} - \sigma}{T_0}\right)}{\text{Log}(0.95)} \quad (15)$$

- *Non-monotonic adaptive cooling.* As the adaptive cooling is combined in the tests with the exponential multiplicative cooling, the decrease factor α that appears in the temperature decrease equation must be also $\alpha = 0.95$.

Analysis of Results

Table 1 shows the cooling parameters used on each instance of the TSP and QAP problems.

For each instance of the problems 100 runs have been made with the nine cooling schedules, computing minimum, maximum and average values, and standard error both of the objective function and of the number of iterations. For limited space reasons we only provide results for the QAP 80-workshops instance (Table 2). Local search results are also included as reference.

Considering both objective quality and number of iterations, we can conclude that the best cooling schedule we have studied is the non-monotonic adaptive cooling schedule based on the one proposed by M. Locatelli (2000), although without significant differences with respect to the exponential multiplicative and quadratic multiplicative cooling schedules.

FUTURE TRENDS

Complying with the former results we propose some research continuation lines on simulated annealing cooling schedules:

- Analyse the influence of the initial temperature in the performance of the algorithm. An interesting idea could be valuing the algorithm behaviour when the temperature is initialized with a percentage between 10% and 90% of the usual estimated value for T_0 .
- Determine an optimal monotonic temperature decrease curve, based on the exponential multiplicative cooling. A possibility could be changing the parameter α dynamically in the temperature decrease equation, with lower initial values ($\alpha = 0.8$) and final values closer to 1 ($\alpha = 0.9$), but achieving an average number of temperature cycles equal to the standard case with constant parameter $\alpha = 0.95$.
- Study new non-monotonic temperature decrease methods, combined with the exponential multiplicative cooling. These methods could be

based, as the Locatelli's one in the comparison, on modifying the temperature according to the distance from the current objective to a reference best objective.

Although these three lines of work are independent, it seems to be clear that the ultimate objective would be integrating the results achieved with these lines, in order to build a high quality combinatorial optimization metaheuristic based on simulated annealing.

CONCLUSION

The main conclusions that can be drawn from the comparison among the cooling schedules of the simulated annealing algorithm are:

- Considering objective quality related to the shape of the temperature decrease curve, we can affirm that simulated annealing works properly with respect to the ability of escape from local minima when the curve has a moderate slope at the initial and central parts of the processing, and softer at the final part of it, just as it occurs in the standard exponential multiplicative cooling. The specific shape (convex, sigmoid) of the curve in the initial and central parts does not seem outstanding.
- Considering execution time, the standard error of the number of iterations seems to be related to the temperature decrease curve tail at the final part of the algorithm. An inversely logarithmic tail produces a softer final temperature fall and a higher standard error, while inversely quadratic and exponential tails cancel out faster, providing the best standard error values of the algorithm.
- Considering the use of a non-monotonic temperature decrease method, we can affirm that not only the utilized criterion does not make worse the general performance of the algorithm but it seems to have a favourable effect that deserves to be taken into account and studied in greater depth.

KEY TERMS

Combinatorial Optimization: Area of the optimization theory whose main aim is the analysis and the algorithmic solving of constrained optimization problems with discrete variables.

Cooling Schedule: Temperature control method in the simulated annealing algorithm. It must specify the initial temperature T_0 , the finite sequence of decreasing values of temperature, and the finite number L of state transitions for each temperature value.

Genetic and Evolutionary Algorithms: Genetic Algorithms (GAs) are approximate optimization algorithms inspired on genetics and the evolution theory. The search space of solutions is seen as a set

of organisms grouped into populations that evolve in time by means of two basic techniques: crossover and mutation. Evolutionary Algorithms (EAs) are especial genetic algorithms that only use mutation as organism generation technique.

Local Search: Local search (LS) is a metaheuristic or general class of approximate optimization algorithms, based on the deterministic heuristic search technique called hill-climbing.

Memetic Algorithms: Memetic Algorithms (MAs) are optimization techniques based on the synergistic combination of ideas taken from other two metaheuristics: genetic algorithms and local search.

Simulated Annealing: Simulated Annealing (SA) is a variant of the metaheuristic of local search that incorporates a stochastic criterion of acceptance of worse quality solutions, in order to prevent the algorithm from being prematurely trapped in local optima.

Taboo Search: Taboo Search (TS) is a metaheuristic superimposed on another heuristic (usually local search or simulated annealing) whose aim is to avoid search cycles by forbidding or penalizing moves which take the solution to points previously visited in the solution space.

Complex Systems Modeling by Cellular Automata

INTRODUCTION

In recent years, the notion of complex systems proved to be a very useful concept to define, describe, and study various natural phenomena observed in a vast number of scientific disciplines. Examples of scientific disciplines that highly benefit from this concept range from physics, mathematics, and computer science through biology and medicine as well as economy, to social sciences and psychology. Various techniques were developed to describe natural phenomena observed in these complex systems. Among these are artificial life, evolutionary computation, swarm intelligence, neural networks, parallel computing, cellular automata, and many others. In this text, we focus our attention to one of them, i.e. ‘cellular automata’.

We present a truly discrete modelling universe, discrete in time, space, and state: Cellular Automata (CAs) (Slood & Hoekstra, 2007, Kroc, 2007, Slood, Chopard & Hoekstra, 2004). It is good to emphasize the importance of CAs in solving certain classes of problems, which are not tractable by other techniques. CAs, despite their simplicity, are able to describe and reproduce many complex phenomena that are closely related to processes such as self-organization and emergence, which are often observed within the above mentioned scientific disciplines.

BACKGROUND

We briefly explain the idea of complex systems and cellular automata and provide references to a number of essential publications in the field.

Complex Systems

The concept of complex systems (CSs) emerged simultaneously and often independently in various scientific disciplines (Fishwick, 2007, Bak, 1996, Resnick, 1997). This could be interpreted as an indication of their universality. Despite the diversity of those fields, there exist a number of common features within all complex systems. Typically a complex system consists of a vast number of simple and locally operating parts, which are mutually interacting and producing a global complex response. Self-organization (Bak, 1996) and emergence, often observed within complex systems, are driven by dissipation of energy and/or information.

Self-organization can be easily explained with ant-colony behavior studies where a vast number of identical processes, called ants, locally interact by physical contact or by using pheromone marked traces. There is no leader providing every ant with information or instructions what it should do. Despite the lack of such a leader or a hierarchy of leaders, ants are able to build complicated ant-colonies, feed their larvae, protect the colony, fight against other colonies, etc. All this is done automatically through a set of simple local interactions among the ants. It is well known that ants are responding on each stimuli by one out of 20 to 40 (depending on ant species) reactions, these are enough to produce the observed complexity.

Emergence is defined as the occurrence of new processes operating at a higher level of abstraction than is the level at which the local rules operate. Each level usually has its own local rules different from rules operating at other levels. An emergent, like an ant-colony, is a product of the process of emergence. There can be a whole hierarchy of emergents, e.g. as in the hu-

man body, that consists of chemicals and DNA, going through polypeptides, proteins, cellular infrastructures and cycles, further on to cells and tissues, organs, and bodies. We see that self-organization and emergence are often closely linked to one another.

Cellular Automata

Early development of CAs dates back to A. Turing, S. Ulam, and J. von Neumann. We can define CA's by four mutually interdependent parts: the lattice and its variables, the neighbourhood, and the local rules (Toffoli & Margolus, 1987, Toffoli, 1984, Vichniac, 1984, Ilachinski, 2001, Wolfram, 2002, Wolfram 1994, Sloat & Hoekstra, 2007, Kroc, 2007). This is briefly explained below.

Lattices and Networks

A lattice is created by a grid of elements, for historical reasons called cells, which can be composed in one, two, three, or higher dimensional space. The lattice is typically composed of uniform cells such as, for instance squares, hexagons or triangles in two dimensions.

CAs operating on networks and graphs represent a generalization of classical CAs, which are working on regular lattices. Networks can be random or regular. Networks can have various topologies, which are classified by the degree of regularity and randomness. A lattice of cells can be interpreted as a regular network of vertices interconnected by edges. When we leave this regularity and allow some random neighbours, more precisely, if a major part of a network is regular and a smaller fraction of it is random, then we enter the domain of small-world networks. The idea of small-world networks provides a unique tool, which allows us to capture many essential properties of naturally observed phenomena especially those linked to social networks and surprisingly to (metabolic and other) networks operating within living cells. Whereas small-world networks are a mixture of regular and random networks, pure random networks have a completely different scope of use. It is worth to mention the concept of scale-free networks, which have a connectivity that does not depend on scale anymore (Kroc, 2007, Sloat, Chopard & Hoekstra, 2004).

Variables

A CA contains an arbitrary number of discrete variables. The number and range of them are dictated by the phenomenon under study. The simplest CAs are built using only one Boolean variable in one dimension (1D), see e.g. (Wolfram, 2002). Some of such simple 1D CAs express even high complexity and are shown to be capable of the universal computation.

Neighbourhoods

The neighbourhood, which is used to evaluate a local rule, is defined by a set of neighbouring cells including the updated cell itself in the case of regular lattices, Figure 1. Neighbours with relative coordinates $[i, j+1]$, $[i-1, j]$, $[i, j-1]$, $[i+1, j]$ of the updated cell $[i, j]$ and located on North, West, South, and East, respectively, define the so called the von Neumann neighbourhood with radius $r=1$. The Moore neighbourhood with radius $r=1$ contains the same cells as the von Neumann neighbourhood plus diagonal cells located at relative positions $[i-1, j+1]$, $[i-1, j-1]$, $[i+1, j-1]$, $[i+1, j+1]$, i.e. North-west, South-west, South-east, and North-east, respectively.

There are many other types of neighbourhoods possible; neighbourhoods can even be spatially or temporally non-uniform. One example is the Margolus neighbourhood, used in diffusion modelling.

The boundaries for each CA can be fixed, reflecting or periodic. Periodic boundary conditions represent infinite lattices. Periodic means that, e.g. in one dimension, the most right cell of a lattice is connected to the most left lattice cell. Fixed boundary cells are kept at predefined values. Reflecting boundary cells reflect values back to the bulk of the lattice.

Local Rules

A local rule defines the evolution of each CA. Usually; it is realized by taking all variables from all cells within the neighbourhood and by evaluation of a set of logical and/or arithmetical operations written in the form of an algorithm. The vector s of those variables is updated according to the following local rule in the case of the von Neumann neighbourhood

$$s[i,j] = f(s[i,j+1], s[i-1,j], s[i,j-1], s[i+1,j]),$$

Figure 1. Four types of neighbourhood is shown on the lattice of 5 x 5 cells: (from left) the von Neumann with $r = 1$, and $r = 2$, the Moore with $r = 1$, and finally a random one

where i represents the x coordinate, j represents y coordinate of the cell, and f the local rule. The updated cell has coordinates $[i, j]$. Figure 1 shows a 5x5 two-dimensional CA with neighbourhoods having various radiuses.

Modelling

Computational modeling is defined as a mathematical, numerical and/or computational description of a naturally observed phenomenon. It is essential in situations where the observed phenomena are not tractable by analytical means. Results are often validated against analytical solutions in special or simplified cases. Its importance has been shown in physics and chemistry and is continuously increasing in new fields such as biology, medicine, sociology, and psychology.

CELLULAR AUTOMATA MODELLING OF COMPLEX SYSTEMS

There is a constant influx of new ideas and approaches enriching the CA method. Within CA modelling of complex systems, there are distinct streams of research and their applications in various disciplines, these are briefly discussed in this section.

Classical cellular automata, with a regular lattice of cells, are used to model ferromagnetic and anti-ferromagnetic materials, solidification, static and dynamic

recrystallization, laser dynamics, traffic flow, escape and pedestrian behaviour, voting processes, self-replication, self-organization, earthquakes, volcano activity, secure coding of information and cryptography, immune systems, living cells and tissue behaviour, morphological development, ecosystems, and many other natural phenomena (Sloot, Chopard & Hoekstra, 2004, Kroc, 2007, Illachinski, 2001). CAs were first used in the modelling of excitable media, such as heart tissue. CAs often outperforms other methods as, e.g., the Monte-Carlo method, especially for highly dissipative systems. The main reason why CAs represents the best choice in modelling of many naturally observed complex phenomena is because CAs are defined above truly spatio-temporally discretized worlds. The inherent CA properties brings new qualities in models that are not principally achievable by other computational techniques.

An example of an advanced CA method is the Lattice Boltzmann method consisting of a triangular network of vertices interconnected by edges where generalized 'liquid particles' move and undergo collisions according a collision table. A model of a gas is created where conservation of mass, momentum and energy during collisions are enforced, which produce a fully discrete and simplified, yet physically correct micro dynamics. When operated in the right limits, they reproduce the incompressible Navier-Stokes equations and therefore are a model for fluid dynamics. Averaged quantities resulting from such simulations correspond

to solutions of the Navier-Stokes equations (Sloot & Hoekstra, 2007, Rivet & Boon, 2001).

Classical CAs, using lattices, have many advantages over other approaches but some known disadvantages have to be mentioned. One of the disadvantages of CAs could be in the use of discrete variables. This restriction is by some authors removed by use of continuous variables, leading to generalized CAs. The biggest disadvantage of classical CAs is often found in the restricted topology of the lattice. Classical regular lattices fail to reproduce properties of many naturally observed phenomena. What led to the following development in CAs.

Generalized cellular automata, Darabos, Giacobini & Tomassini in (Kroc, 2007), are built on general networks, which are represented by regular, random, scale-free networks or small-world networks. A regular network can be created from a classical CA and its lattice where each cell represents a node and each neighbour is linked by an edge. A random graph is made from nodes that have randomly chosen nodes as neighbours. Within scale-free networks, some nodes are highly connected to other points whereas other nodes are less connected. Their properties are independent of their size. The distribution of degree of links at a node follow a power law relationship $P(k) = k^{-\gamma}$, where $P(k)$ is the probability that a node is connect to k other nodes. The coefficient γ is in most cases between 2 and 3. Those networks occur for instance in the Internet, in social networks, and in biologically produced networks such as gene regulatory networks within living cells or food chains within ecosystems (Sloot, Ivanov, Boukhanovsky, van de Vijver & Boucher, 2007).

In general, the behaviour of a given CA is unpredictable what is often used in cryptography. There exist a number of mostly statistical techniques enabling to study the behaviour of given CA but none of them is exact. The easiest way, and often the only one, to find out the state of a CA is its execution.

CASE STUDIES

Understanding morphological growth and branching of stony corals with the lattice Boltzmann method is a good example of studying natural complex system with CAs (Kaandorp, Lowe, Frenkel & Sloot, 1996, Kaandorp, Sloot, Merks, Bak, Vermeij, & Maier, 2005). A deep insight into those processes is important to assess the

role of corals in marine ecosystems and, e.g., its relation to global climate changes. Simulation of growth and branching of a coral involves multiphysics processes such as, nutrient diffusion, fluid flow, light absorption by the zooxanthele that live in symbiosis with the coral polyps, as well as mechanical stress.

It is demonstrated that nutrient gradients determine the morphogenesis of branching of phototropic corals. In this specific case, we deal with diffusion-limited processes fully determining the morphological shape of the growing corals. It is known from tank experiments and simulation studies that those diffusion dominant regions operate for relatively high flow velocities. It has been demonstrated that simulated coral morphologies are indistinguishable from real corals (Kaandorp, Sloot, Merks, Bak, Vermeij, & Maier, 2005), Figure 3.

Modelling of dynamic recrystallization represents another living application of CAs within the field of solid state physics (Kroc, 2002). Metals having polycrystalline form, composed from many single crystals, are deformed at elevated temperatures. The stored energy is increasing due to deformation, which is in turn released by recrystallization, where nuclei grow and form new grains. Growth is driven by the release of stored energy. The response of deformed polycrystalline material is reflected by complex changes within the microstructure and deformation curve.

Stress-strain curves measured during deformation of metallic samples exhibits either single peak or multiple peak behaviour. This complex response of deformed material is a direct result of concurrent processes operating within deformed material. CAs, so far, represents the only computational technique, which is able to describe such complex material behaviour (Kroc, 2002), Figure 3.

FUTURE TRENDS

There is a number of distinct tracks within CAs research with a constant flux of new discoveries (Kroc, 2007, Sloot & Hoekstra, 2007). CAs are used to model physical phenomena but they are increasingly used to model biological, medical and social phenomena. Most CAs are designed by hand but the future requires development of automatic and self-adjusting optimization techniques to design local rules according to the needs of the described natural phenomena.

Figure 2. Morphological growth of coral *Mandraxis mirabilis* obtained through 3D visualization of a CT-scan of the coral (top) and two simulated growth forms (bottom) with different morphological shapes are depicted (Kaandorp, Sloot, Merks, Bak, Vermeij, & Maier, 2005). Simulated structures are indistinguishable from real corals.

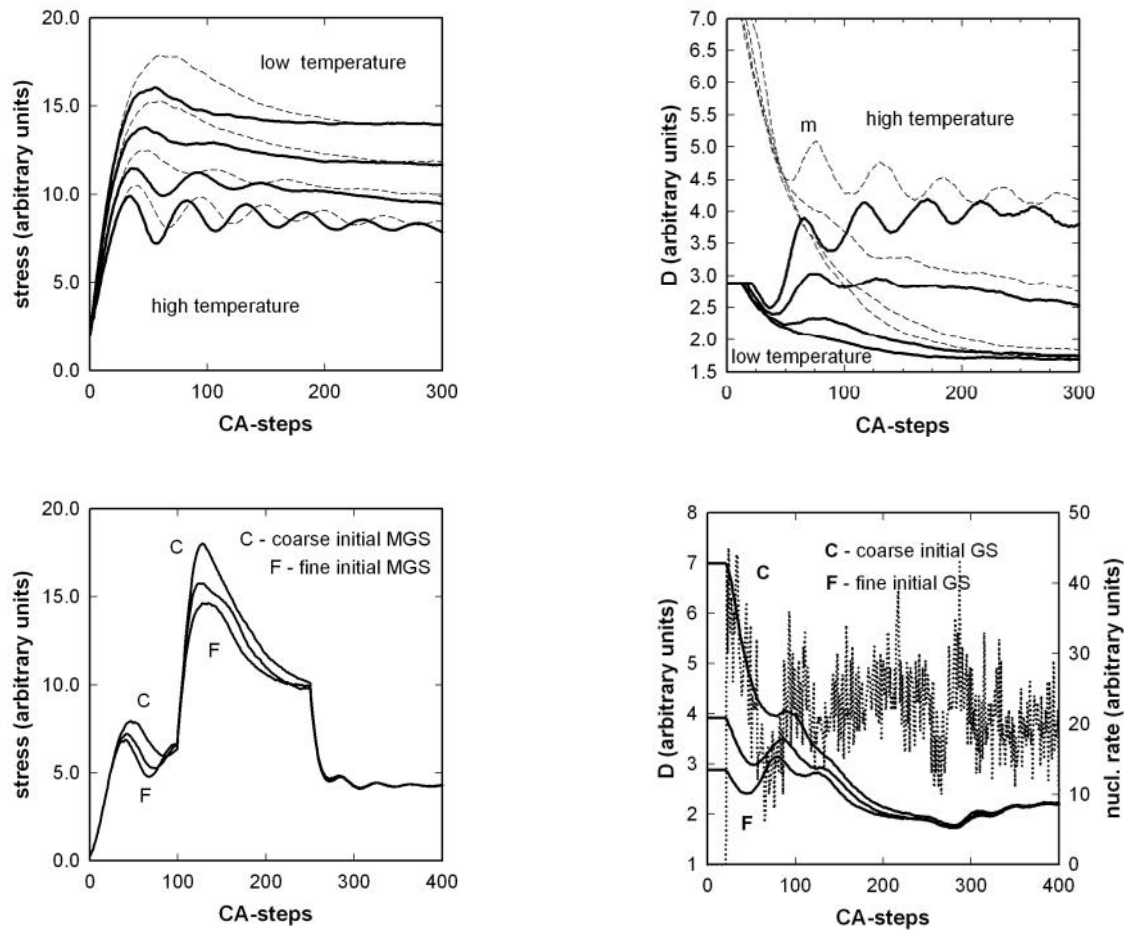

It is important to stress that the CA technique is bringing a cross-fertilization among many scientific disciplines. It happened many times in past that two or more very similar techniques were developed in distinct scientific fields such as, e.g. physics and social science.

The spatial structure of CAs is evolving from regular lattices to networked CAs Darabos, Giacobini, Tomassini in (Kroc, 2007), and to multilevel CAs (Hoekstra, Lorentz, Fakone & Chopard, 2007). Updating schemes of CAs will address in the future two regimes: synchronous (the classical one), and asynchronous (Sloot, Overeinder & Schoneveld, 2001).

CONCLUSIONS

We briefly discussed complex systems and demonstrate the usefulness of cellular automata in modelling those systems. It has been shown that cellular automata provide a simple but an extremely efficient numerical technique, which is able to describe and simulate such complicated behaviour as self-organization and emergence. This extraordinary combination of simplicity and expressivity brings a constant flux of new discoveries in description of many naturally observed phenomena in almost all scientific fields.

Figure 3. Simulation of dynamic recrystallization is represented by: stress–strain curves (top-left), relevant mean grain size D –strain curves (top-right), an abrupt change loading strain rate (bottom-left), and relevant D –strain curves (bottom-right). Strain is represented by the number of CA steps (Kroc, 2002).

Finally, it is good to emphasize that CAs represent a generic method often used in the development of prototypes of completely new numerical methods describing naturally observed phenomena. We believe that CAs have a great potential for the future development of computational modelling and the understanding of the dynamics of complex systems.

KEY TERMS

Cellular Automaton: (plural: cellular automata.) A cellular automaton is defined as a lattice (network) of cells (automata) where each automaton contains a set of discrete variables, which are updated according to a local rule operating above neighbours of given cell in discrete time steps. Cellular automata are typically used as simplified but not simple models of complex systems.

Generalized Cellular Automaton: It is based on use of networks instead of regular lattices.

Complex Network: Most of biological and social networks reflect topological properties not observed within simple networks (regular, random). Two examples are small-world and scale-free networks.

Complex System: A typical complex system consists of a vast number of identical copies of several generic processes, which are operating and interacting only locally or with a limited number of not necessary

close neighbours. There is no global leader or controller associated to such systems and the resulting behaviour is usually very complex.

Emergence: Emergence is defined as the occurrence of new processes operating at a higher level of abstraction than is the level at which the local rules operate. A typical example is an ant colony where this large complex structure emerges through local interactions of ants. For example, a whole hierarchy of emergents exists and operates in a human body. An emergent is the product of an emergence process.

Lattice Gas Automata: Typically, it is a triangular network of vertices interconnected by edges where generalized liquid particles move and undergo collisions. Averaged quantities resulting from such simulations correspond to solutions of the Navier-Stokes equations.

Modelling: It is a description of naturally observed phenomena using analytical, numerical, and/or computational methods. Computational modelling is classically used in such fields as, e.g. physics, engineering. Its importance is increasing in other fields such as biology, medicine, sociology, and psychology.

Random Network: A neighbourhood of a vertex is created by a set of randomly chosen links to neighbouring vertices (elements) within a network of vertices.

Regular Lattice: A perfectly regular and uniform neighbourhood for each lattice element called cell characterizes such lattices.

Self-Organization: Self-organization is a process typically occurring within complex systems where a system is continuously fed by energy, which is transformed into a new system state or operational mode by a dissipation of energy and/or information.

Self-Organized Criticality: A complex system expressing SOC is continuously fed by energy where release of it is discrete and typically occurs in the form of avalanches. Most of its time, SOC operates at a critical point where avalanches occur. Earthquakes and volcano eruptions represent prototypical examples of SOC observed in many naturally observed phenomena.

Small-World Network: A mixture of two different types of connections within each neighbourhood characterizes small-worlds. Typically, a neighbourhood of given vertex is composed of a greater fraction of neighbours having regular short-range connectivity (regular network) and a smaller fraction of random connections (random network). Such type of neighbourhood provides unique properties to each model built on the top of it.

Complex-Valued Neural Networks

Tohru Nitta

AIST, Japan

C

INTRODUCTION

The usual real-valued artificial neural networks have been applied to various fields such as telecommunications, robotics, bioinformatics, image processing and speech recognition, in which complex numbers (two dimensions) are often used with the Fourier transformation. This indicates the usefulness of complex-valued neural networks whose input and output signals and parameters such as weights and thresholds are all complex numbers, which are an extension of the usual real-valued neural networks. In addition, in the human brain, an action potential may have different pulse patterns, and the distance between pulses may be different. This suggests that it is appropriate to introduce complex numbers representing phase and amplitude into neural networks.

Aizenberg, Ivaskiv, Pospelov and Hudiakov (1971) (former Soviet Union) proposed a complex-valued neuron model for the first time, and although it was only available in Russian literature, their work can now be read in English (Aizenberg, Aizenberg & Vandewalle, 2000). Prior to that time, most researchers other than Russians had assumed that the first persons to propose a complex-valued neuron were Widrow, McCool and Ball (1975). Interest in the field of neural networks started to grow around 1990, and various types of complex-valued neural network models were subsequently proposed. Since then, their characteristics have been researched, making it possible to solve some problems which could not be solved with the real-valued neuron, and to solve many complicated problems more simply and efficiently.

BACKGROUND

The generic definition of a complex-valued neuron is as follows. The input signals, weights, thresholds and

output signals are all complex numbers. The net input U_n to a complex-valued neuron n is defined as:

$$U_n = \sum_m W_{nm} X_m + V_n \quad (1)$$

where W_{nm} is the complex-valued weight connecting complex-valued neurons n and m , X_m is the complex-valued input signal from the complex-valued neuron m , and V_n is the complex-valued threshold of the neuron n . The output value of the neuron n is given by $f_c(U_n)$ where $f_c: C \rightarrow C$ is called *activation function* (C denotes the set of complex numbers). Various types of activation functions used in the complex-valued neuron have been proposed, which influence the properties of the complex-valued neuron, and a complex-valued neural network consists of such complex-valued neurons.

For example, the component-wise activation function or real-imaginary type activation function is often used (Nitta & Furuya, 1991; Benvenuto & Piazza, 1992; Nitta, 1997), which is defined as follows:

$$f_c(z) = f_R(x) + i f_R(y) \quad (2)$$

where $f_R(u) = 1/(1+\exp(-u))$, $u \in \mathbf{R}$ (\mathbf{R} denotes the set of real numbers), i denotes $\sqrt{-1}$, and the net input U_n is converted into its real and imaginary parts as follows:

$$U_n = x + iy = z. \quad (3)$$

That is, the real and imaginary parts of an output of a neuron mean the sigmoid functions of the real part x and imaginary part y of the net input z to the neuron, respectively.

Note that the component-wise activation function (eqn (2)) is bounded but non-regular as a complex-valued function because the Cauchy-Riemann equations do not hold. Here, as several researchers have pointed out (Georgiou & Koutsougeras, 1992; Nitta, 1997) in the complex region, we should recall the Liouville's

theorem, which states that if a function g is regular at all $z \in \mathbb{C}$ and bounded, then g is a constant function. That is, we need to choose either regularity or boundedness for an activation function of complex-valued neurons. In addition, it has been proved that the complex-valued neural network with the component-wise activation function (eqn (2)) can approximate any continuous complex-valued function, whereas a network with a regular activation function (for example, $f_c(z) = 1/(1+\exp(-z))$ (Kim & Guest, 1990), and $f_c(z) = \tanh(z)$ (Kim & Adali, 2003)) cannot approximate any non-regular complex-valued function (Arena, Fortuna, Re & Xibilia, 1993; Arena, Fortuna, Muscato & Xibilia, 1998). That is, the complex-valued neural network with the non-regular activation function (eqn (2)) is a universal approximator, but a network with a regular activation function is not. It should be noted here that the complex-valued neural network with a regular complex-valued activation function such as $f_c(z) = \tanh(z)$ with the poles can be a universal approximator on the compact subsets of the deleted neighbourhood of the poles (Kim & Adali, 2003). This fact is very important theoretically, however, unfortunately the complex-valued neural network for the analysis is not usual, that is, the output of the hidden neuron is defined as the product of several activation functions. Thus, the statement seems to be insufficient to compare with the case of component-wise complex-valued activation function. Thus, the ability of complex-valued neural networks to approximate complex-valued functions depends heavily on the regularity of activation functions used.

On the other hand, several complex-valued activation functions based on polar coordinates have been proposed. For example, Hirose (1992) proposed the following amplitude-phase type activation function:

$$f_c(z) = \tanh\left(\frac{\alpha}{m}\right) \cdot \exp(i\beta), \quad z = \alpha \cdot \exp(i\beta), \quad (4)$$

where m is a constant. Although this amplitude-phase activation function is not regular, Hirose noted that the non-regularity did not cause serious problems in real applications and that the amplitude-phase framework is suitable for applications in many engineering fields such as optical information processing systems, and amplitude modulation, phase modulation and frequency modulation in electromagnetic wave communications

and radar. Aizenberg et al. (2000) proposed the following activation function:

$$f_c(z) = \exp\left(i \frac{2\pi j}{k}\right), \quad \text{if } \frac{2\pi j}{k} \leq \beta < \frac{2\pi(j+1)}{k}, \\ z = \alpha \cdot \exp(i\beta), \quad j = 0, 1, \dots, k-1 \quad (5)$$

where k is a constant. Eqn (5) can be regarded as a type of amplitude-phase activation functions. Only phase information is used and the amplitude information is discarded, however, many successful applications show that the activation function is sufficient.

INHERENT PROPERTIES OF THE MULTI-LAYERED TYPE COMPLEX-VALUED NEURAL NETWORK

This article presents the essential differences between multi-layered type real-valued neural networks and multi-layered type complex-valued neural networks, which are very important because they expand the real application fields of the multi-layered type complex-valued neural networks. To the author's knowledge, the inherent properties of complex-valued neural networks with regular complex-valued activation functions have not been revealed except their learning performance so far. Thus, only the inherent properties of the complex-valued neural network with the non-regular complex-valued activation function (eqn (2)) are mainly described: (a) the learning performance, (b) the ability to transform geometric figures, and (c) the orthogonal decision boundary.

Learning Performance

In the applications of multi-layered type real-valued neural networks, the error back-propagation learning algorithm (called here, *Real-BP*) (Rumelhart, Hinton & Williams, 1986) has often been used. Naturally, the complex-valued version of the Real-BP (called here, *Complex-BP*) can be considered, and was actually proposed by several researchers (Kim & Guest, 1990; Nitta & Furuya, 1991; Benvenuto & Piazza, 1992; Georgiou & Koutsougeras, 1992; Nitta, 1993, 1997; Kim & Adali, 2003). This algorithm enables the network to learn complex-valued patterns naturally.

It is known that the learning speed of the Complex-BP algorithm is faster than that of the Real-BP algorithm. Nitta (1991, 1997) showed in some experiments on learning complex-valued patterns that the learning speed is several times faster than that of the conventional technique, while the space complexity (i.e., the number of learnable parameters needed) is only about half that of Real-BP. Furthermore, De Azevedo, Travessa and Argoud (2005) applied the Complex-BP algorithm of the literature (Nitta, 1997) to the recognition and classification of epileptiform patterns in EEG, in particular, dealing with spike and eye-blink patterns, and reconfirmed the superiority of the learning speed of the Complex-BP described above. As for the regular complex-valued activation function, Kim and Adali (2003) compared the learning speed of the Complex-BP using nine regular complex-valued activation functions with those of the Complex-BP using three non-regular complex-valued activation functions (including eqn (4)) through a computer simulation for a simple nonlinear system identification example. The experimental results suggested that the Complex-BP with the regular

activation function $f_c(z) = \arcsin h(z)$ was the fastest among them.

Ability to Transform Geometric Figures

The Complex-BP with the non-regular complex-valued activation function (eqn (2)) can transform geometric figures, e.g. rotation, similarity transformation and parallel displacement of straight lines, circles, etc., whereas the Real-BP cannot (Nitta, 1991, 1993, 1997). Numerical experiments suggested that the behaviour of a Complex-BP network which learned the transformation of geometric figures was related to the Identity Theorem in complex analysis.

Only an illustrative example on a *rotation* is given below. In the computer simulation, a 1-6-1 three-layered complex-valued neural network was used, which transformed a point (x, y) into (x', y') in the complex plane. Although the Complex-BP network generates a value z within the range $0 < \text{Re}[z], \text{Im}[z] < 1$ due to the activation function used (eqn (2)), for the sake of convenience it is presented in the figure given below as having a transformed value within the range $-1 < \text{Re}[z], \text{Im}[z] < 1$. The learning rate used in the experiment was 0.5. The initial real and imaginary components of the weights and the thresholds were chosen to be

random real numbers between 0 and 1. The experiment consisted of two parts: a training step, followed by a test step. The training step consisted of learning a set of (complex-valued) weights and thresholds, such that the input set of (straight line) points (indicated by black circles in Fig. 1) gave as output, the (straight line) points (indicated by white circles) rotated counterclockwise over $\pi/2$ radians. Input and output pairs were presented 1,000 times in the training step. These complex-valued weights and thresholds were then used in a test step, in which the input points lying on a straight line (indicated by black triangles in Fig. 1) would hopefully be mapped to an output set of points lying on the straight line (indicated by white triangles) rotated counterclockwise over $\pi/2$ radians. The actual output test points for the Complex-BP did, indeed, lie on the straight line (indicated by white squares). It appears that the complex-valued network has learned to generalize the transformation of each point $Z_k (= r_k \exp[i\theta_k])$ into $Z_k \exp[i\alpha] (= r_k \exp[i(\theta_k + \alpha)])$, i.e., the angle of each complex-valued point is updated by a complex-valued factor $\exp[i\alpha]$, however, the absolute length of each input point is preserved. In the above experiment, the 11 training input points lay on the line $y = -x + 1$ ($0 \leq x \leq 1$) and the 11 training output points lay on the line $y = x + 1$ ($-1 \leq x \leq 0$). The seven test input points lay on the line $y = 0.2$ ($-0.9 \leq x \leq 0.3$). The desired output test points should lie on the line $x = -0.2$.

Watanabe, Yazawa, Miyauchi and Miyauchi (1994) applied the Complex-BP in the field of computer vision. They successfully used the ability to transform geometric figures of the Complex-BP network to complement the 2D velocity vector field on an image, which was derived from a set of images and called an *optical flow*. The ability to transform the geometric figure of the Complex-BP can also be used to generate fractal images. Actually, Miura and Aiyoshi (2003) applied the Complex-BP to the generation of fractal images and showed in computer simulations that some fractal images such as snow crystals could be obtained with high accuracy where the iterated function systems (IFS) were constructed using the ability to transform geometric figure of the Complex-BP.

Orthogonal Decision Boundary

The decision boundary of the complex-valued neuron with the non-regular complex-valued activation function (eqn (2)) has a different structure from that

of the real-valued neuron. Consider a complex-valued neuron with M input neurons. Let the weights denote $\mathbf{w} = [w_1 \dots w_M] = \mathbf{w}^r + i \mathbf{w}^i$, $\mathbf{w}^r = [w_1^r \dots w_M^r]$, $\mathbf{w}^i = [w_1^i \dots w_M^i]$ and let the threshold denote $\theta = \theta^r + i \theta^i$. Then, for M input signals (complex numbers) $\mathbf{z} = [z_1 \dots z_M] = \mathbf{x} + i\mathbf{y}$, $\mathbf{x} = [x_1 \dots x_M]$, $\mathbf{y} = [y_1 \dots y_M]$, the complex-valued neuron generates

$$X + iY = f_r \left([\mathbf{w}^r \quad -\mathbf{w}^i] \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} + \theta^r \right) + i f_r \left([\mathbf{w}^i \quad \mathbf{w}^r] \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} + \theta^i \right) \quad (6)$$

as an output. Here, for any two constants $C^R, C^I \in (0, 1)$, let

$$X(\mathbf{x}, \mathbf{y}) = f_r \left([\mathbf{w}^r \quad -\mathbf{w}^i] \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} + \theta^r \right) = C^R, \quad (7)$$

$$Y(\mathbf{x}, \mathbf{y}) = f_r \left([\mathbf{w}^i \quad \mathbf{w}^r] \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} + \theta^i \right) = C^I. \quad (8)$$

Note here that eqn (7) is the decision boundary for the *real part* of an output of the complex-valued neuron with M inputs. That is, input signals $(\mathbf{x}, \mathbf{y}) \in \mathbf{R}^{2M}$ are classified into two decision regions $\{(\mathbf{x}, \mathbf{y}) \in \mathbf{R}^{2M} \mid X(\mathbf{x}, \mathbf{y}) \geq C^R\}$ and $\{(\mathbf{x}, \mathbf{y}) \in \mathbf{R}^{2M} \mid X(\mathbf{x}, \mathbf{y}) < C^R\}$ by the hypersurface given by eqn (7). Similarly, eqn (8) is the decision boundary for the *imaginary part*. Noting that the inner product of the normal vectors of the decision boundaries (eqns (7) and (8)) is zero, we find that the decision boundary for the real part of an output of a complex-valued neuron and that for the imaginary part intersect orthogonally.

As is well known, the XOR problem and the detection of symmetry problem cannot be solved with a single real-valued neuron (Rumelhart, Hinton & Williams, 1986). Contrary to expectation, it was proved that such problems could be solved by a single complex-valued neuron with the orthogonal decision boundary, which revealed the potent computational power of complex-valued neural networks (Nitta, 2004a).

FUTURE TRENDS

Many application results (Hirose, 2003) such as associative memories, adaptive filters, multi-user communication and radar image processing suggest directions for future research on complex-valued neural networks.

It is natural that the inherent properties of the multi-layered type complex-valued neural network with non-regular complex-valued activation function (eqn (2)) are not limited to the ones described above. Furthermore, to the author's knowledge, the inherent properties except the learning performance of recurrent type complex-valued neural networks have not been reported. The same is also true of the complex-valued neural network with regular complex-valued activation functions. Such exploration will expand the application fields of complex-valued neural networks.

In the meantime, efforts have already been made to increase the dimensionality of neural networks, for example, three dimensions (Nitta, 2006), quaternions (Arena, Fortuna, Muscato & Xibilia, 1998; Isokawa, Kusakabe, Matsui & Peper, 2003; Nitta, 2004b), Clifford algebras (Pearson & Bisset, 1992; Buchholz & Sommer, 2001), and N dimensions (Nitta, 2007), which is a new direction for enhancing the ability of neural networks.

CONCLUSION

This article outlined the inherent properties of complex-valued neural networks, especially those of the case with non-regular complex-valued activation functions, that is, (a) the learning performance, (b) the ability to transform geometric figures, and (c) the orthogonal decision boundary. Successful applications of such networks were also described.

KEY TERMS

Artificial Neural Network: A network composed of artificial neurons. Artificial neural networks can be trained to find nonlinear relationships in data.

Back-Propagation Algorithm: A supervised learning technique used for training neural networks, based on minimizing the error between the actual outputs and the desired outputs.

Clifford Algebras: An associative algebra, which can be thought of as one of the possible generalizations of complex numbers and quaternions.

Complex Number: A number of the form $a + ib$ where a and b are real numbers, and i is the imaginary unit such that $i^2 = -1$. a is called the *real part*, and b the *imaginary part*.

Decision Boundary: A boundary which pattern classifiers such as the real-valued neural network use to classify input patterns into several classes. It generally consists of hypersurfaces.

Identity Theorem: A theorem for regular complex functions: given two regular functions f and g on a connected open set D , if $f = g$ on some neighborhood of z that is in D , then $f = g$ on D .

Quaternion: A four-dimensional number which is a non-commutative extension of complex numbers.

Regular Complex Function: A complex function that is complex-differentiable at every point.

Figure 1. Rotation of a straight line. A black circle denotes an input training point, a white circle an output training point, a black triangle an input test point, a white triangle a desired output test point, and a white square an output test point generated by the Complex-BP network.

Component Analysis in Artificial Vision

Oscar Déniz Suárez

University of Las Palmas de Gran Canaria, Spain

Gloria Bueno García

INTRODUCTION

The typical recognition/**classification** framework in Artificial Vision uses a set of object features for discrimination. Features can be either numerical measures or nominal values. Once obtained, these feature values are used to classify the object. The output of the classification is a label for the object (Mitchell, 1997).

The classifier is usually built from a set of “**training**” samples. This is a set of examples that comprise feature values and their corresponding labels. Once trained, the classifier can produce labels for new samples that are not in the training set.

Obviously, the extracted features must be discriminative. Finding a good set of features, however, may not be an easy task. Consider for example, the face recognition problem: recognize a person using the image of his/her face. This is currently a hot topic of research within the Artificial Vision community, see the surveys (Chellappa et al, 1995), (Samal & Iyengar, 1992) and (Chellappa & Zhao, 2005). In this problem, the available features are all of the pixels in the image. However, only a number of these pixels are normally useful for discrimination. Some pixels are background, hair, shoulders, etc. Even inside the head zone of the image some pixels are less useful than others. The eye zone, for example, is known to be more informative than the forehead or cheeks (Wallraven et al, 2005). This means that some features (pixels) may actually increase recognition error, for they may confuse the classifier.

Apart from performance, from a computational cost point of view it is desirable to use a minimum number of features. If fed with a large number of features, the classifier will take too long to train or classify.

BACKGROUND

Feature Selection aims at identifying the most **informative features**. Once we have a measure of “*informativeness*” for each feature, a subset of them can be used for classifying. In this case, the features remain the same, only a selection is made. The topic of feature selection has been extensively studied within the Machine Learning community (Duda et al, 2000). Alternatively, in Feature Extraction a new set of features is created from the original set. In both cases the objective is both reducing the number of available features and using the most discriminative ones.

The following sections describe two techniques for Feature Extraction: Principal Component Analysis and Independent Component Analysis. Linear Discriminant Analysis (LDA) is a similar dimensionality reduction technique that will not be covered here for space reasons, we refer the reader to the classical text (Duda et al., 2000).

Figure 1.

As an example problem we will consider face recognition. The face recognition problem is particularly interesting here because of a number of reasons. First, it is a topic of increasingly active research in Artificial Vision, with potential applications in many domains. Second, it has images as input, see Figure 1 from the Yale Face Database (Belhumeur et al, 1997), which means that some kind of feature processing/selection must be done previous to classification.

PRINCIPAL COMPONENT ANALYSIS

Principal Component Analysis (PCA), see (Turk & Pentland, 1991), is an orthogonal linear transformation of the input feature space. PCA transforms the data to a new coordinate system in which the data variances in the new dimensions is maximized. Figure 2 shows a 2-class set of samples in a 2-feature space. These data have a certain **variance** along the horizontal and vertical axes. PCA maps the samples to a new orthogonal coordinate system, shown in bold, in which the sample variances are maximized. The new coordinate system is centered on the data mean.

The new set of features (note that the coordinate axes are features) is better from a discrimination point

of view, for samples of the two classes can be readily separated. Besides, the PCA transform provides an ordering of features, from the most discriminative (in terms of variance) to the least. This means that we can select and use only a subset of them. In the figure above, for example, the coordinate with the largest axis is the most discriminative.

When the input space is an image, as in face recognition, training images are stored in a matrix T . Each row of T contains a training image (the image rows are laid consecutively, forming a vector). Thus, each image pixel is considered a feature. Let there be n training images. PCA can then be done in the following steps:

1. Subtract the mean image vector m from T , where:

$$m = \frac{1}{n} \sum_i x_i$$

2. Calculate the covariance matrix C :

$$C = \frac{1}{n} \sum_i (x_i - m)(x_i - m)^T$$

3. Perform Singular Value Decomposition over C , which gives an orthogonal transform matrix W

Figure 2.

Figure 3.

4. Choose a set of “eigenfaces” (see below)

The new feature axes are the columns of W . These features can be considered as images (i.e. by arranging each vector as a matrix), and are commonly called basis images or *eigenfaces* within the face recognition community. The intensity of the pixels of these images represents their weight or contribution in the axis. Figure 3 shows the typical aspect of eigenfaces.

Normally, in step 4 above only the best K eigenvectors are selected and used in the classifier. That is achieved by discarding a number of columns in W . Once we have the appropriate transform matrix, any set X of images can be transformed to this new space simply by:

1. Subtract the mean m from the images in X
2. Calculate $Y = X \cdot W$

The transformed image vectors Y are the new feature vectors that the classifier will use for training and/or classifying.

INDEPENDENT COMPONENT ANALYSIS

Independent Component Analysis is a feature extraction technique based in extracting statistically independent variables from a mixture of them (Jutten & Hérault,

1991, Comon, 1994). ICA has been successfully applied to many different problems such as MEG and EEG data analysis, **blind source separation** (i.e. separating mixtures of sound signals simultaneously picked up by several microphones), finding hidden factors in financial data and face recognition, see (Bell & Sejnowski, 1995).

The ICA technique aims at finding a linear transform for the input data so that the transformed data is as statistically independent as possible. **Statistical independence** implies **decorrelation** (but note that the opposite is not true). Therefore, ICA can be considered a generalization of PCA.

The basis images obtained with ICA are more local than those obtained with PCA, which suggests that they can lead to more precise representations. Figure 4 shows the typical basis images obtained with ICA.

ICA routines are available in a number of different implementations, particularly for Matlab. ICA has a higher computational cost than PCA. FastICA is the most efficient implementation to date, see (Gävert et al, 2005).

As opposed to PCA, ICA does not provide an intrinsic order for the representation coefficients of the face images, which does not help when extracting a subset of K features. In (Bartlett & Sejnowski, 1997) the best results were obtained with an order based on the ratio of between-class to within-class variance for each coefficient:

Figure 4.

$$r_j = \frac{V}{v} = \frac{\sum_j (\bar{x}_j - \bar{x})^2}{\sum_j \sum_i (x_{ji} - \bar{x})^2}$$

where V is the variance of the j class mean and v is the sum of the variances within each class.

FUTURE TRENDS

PCA has been shown to be an invaluable tool in Artificial Vision. Since the seminal work of (Turk & Pentland, 1991) PCA-based methods are considered standard baselines in the problem of face recognition. Many other techniques have evolved from it: robust PCA, nonlinear PCA, incremental PCA, kernel PCA, probabilistic PCA, etc.

As mentioned above, ICA can be considered an extension of PCA. Some authors have shown that in certain cases the ICA transformation does not provide performance gain over PCA when a “good” classifier is used (like Support Vector Machines), see (Déniz et al, 2003). This may be of practical significance, since PCA is faster than ICA. ICA is not being used as extensively within the Artificial Vision community as it is in other disciplines like signal processing, especially where the problem of interest is signal separation.

On the other hand, **Graph Embedding** (Yan et al, 2005) is a framework recently proposed that constitutes an elegant generalization of PCA, LDA (Linear Discriminant Analysis), LPP (Locality Preserving Projections) and other dimensionality reduction techniques. As well as providing a common formulation, it facilitates the designing of new dimensionality reduction algorithms based on new criteria.

CONCLUSION

Component analysis is a useful tool for Artificial Vision Researchers. PCA, in particular, can now be considered indispensable to reduce the high dimensionality of images. Both computation time and error ratios can be reduced. This article has described both PCA and the related technique ICA, focusing on their application to the face recognition problem.

Both PCA and ICA act as a feature extraction stage, previous to training and classification. ICA is computa-

tionally more demanding, however its efficiency over PCA has not yet been established in the context of face recognition. Thus, it is foreseeable that the eigenfaces technique introduced by Turk and Pentland remains as a face recognition baseline in the near future.

KEY TERMS

Classifier: Algorithm that produces class labels as output, from a set of features of an object. A classifier, for example, is used to classify certain features extracted from a face image and provide a label (an identity of the individual).

Eigenface: A basis vector of the PCA transform, when applied to face images.

Face Recognition: The AV problem of recognizing an individual from one or more images of his/her face.

Feature Extraction: The process by which a new set of discriminative features is obtained from those available. Classification is performed using the new set of features.

Feature Selection: The process by which a subset of the available features (usually the most discriminative ones) is selected for classification.

Independent Component Analysis: Feature extraction technique in which the statistical independence of the data is maximized.

Principal Component Analysis: Feature extraction technique in which the variance of the data is maximized. It provides a new feature space in which the dimensions are ordered by sample correlation. Thus, a subset of these dimensions can be chosen in which samples are minimally correlated.

Computational Methods in Biomedical Imaging

Michele Piana

Universita' di Verona, Italy

INTRODUCTION

Biomedical imaging represents a practical and conceptual revolution in the applied sciences of the last thirty years. Two basic ingredients permitted such a breakthrough: the technological development of hardware for the collection of detailed information on the organ under investigation in a less and less invasive fashion; the formulation and application of sophisticated mathematical tools for signal processing within a methodological setting of truly interdisciplinary flavor.

A typical acquisition procedure in biomedical imaging requires the probing of the biological tissue by means of some emitted, reflected or transmitted radiation. Then a mathematical model describing the image formation process is introduced and computational methods for the numerical solution of the model equations are formulated. Finally, methods based on or inspired by Artificial Intelligence (AI) frameworks like machine learning are applied to the reconstructed images in order to extract clinically helpful information.

Important issues in this research activity are the intrinsic numerical instability of the reconstruction problem, the convergence properties and the computational complexity of the image processing algorithms. Such issues will be discussed in the following with the help of several examples of notable significance in the biomedical practice.

BACKGROUND

The first breakthrough in the theory and practice of recent biomedical imaging is represented by X-ray Computerized **Tomography** (CT) (Hounsfield, 1973). On October 11 1979 Allan Cormack and Godfrey Hounsfield gained the Nobel Prize in medicine for the development of computer assisted tomography. In the press release motivating the award, the Nobel Assembly of the Karolinska Institut wrote that in

this revolutionary diagnostic tool “the signals[...]are stored and mathematically analyzed in a computer. The computer is programmed to reconstruct an image of the examined cross-section by solving a large number of equations including a corresponding number of unknowns”. Starting from this crucial milestone, biomedical imaging has represented a lively melting pot of clinical practice, experimental physics, computer science and applied mathematics, providing mankind of numerous non-invasive and effective instruments for early detection of diseases, and scientist of a prolific and exciting area for research activity.

The main imaging modalities in biomedicine can be grouped into two families according to the kind of information content they provide.

- **Structural imaging:** the image provides information on the anatomical features of the tissue without investigating the organic metabolism. Structural modalities are typically characterized by a notable spatial resolution but are ineffective in reconstructing the dynamical evolution of the imaging parameters. Further to X-ray CT, other examples of such approach are Fluorescence Microscopy (Rost & Oldfield, 2000), Ultrasound Tomography (Greenleaf, Gisvold & Bahn, 1982), structural Magnetic Resonance Imaging (MRI) (Haacke, Brown, Venkatesan & Thompson, 1999) and some kinds of prototypal non-linear tomographies like Microwave Tomography (Boulyshev, Souvorov, Semenov, Posukh & Sizov, 2004), Diffraction Tomography (Guo & Devaney, 2005), Electrical Impedance Tomography (Cheney, Isaacson & Newell, 1999) and Optical Tomography (Arridge, 1999).
- **Functional imaging:** during the acquisition many different sets of signals are recorded according to a precisely established temporal paradigm. The resulting images can provide information on metabolic deficiencies and functional diseases

but are typically characterized by a spatial resolution which is lower (sometimes much lower) than the one of anatomical imaging. Emission tomographies like Single Photon Emission Computerized Tomography (SPECT) (Duncan, 1997) or Positron Emission Tomography (PET) (Valk, Bailey, Townsend & Maisey, 2004) and Magnetic Resonance Imaging in its functional setup (fMRI) (Huettel, Song & McCarthy, 2004) are examples of these dynamical techniques together with Electro- and Magnetoencephalography (EEG and MEG) (Zschocke & Speckmann, 1993; Hamalainen, Hari, Ilmoniemi, Knuutila & Lounasmaa, 1993), which reproduce the neural activity at a millisecond time scale and in a completely non-invasive fashion.

In all these imaging modalities the correct mathematical modeling of the imaging problem, the formulation of computational algorithms for the solution of the model equations and the application of image processing algorithms for data interpretation are the crucial steps which allow the exploitment of the visual information from the measured raw data.

MAIN FOCUS

From a mathematical viewpoint the **inverse problem** of synthesizing the biological information in a visual form from the collected radiation is characterized by a peculiar pathology.

The concept of **ill-posedness** has been introduced by Jules Hadamard (Hadamard, 1923) to indicate mathematical problems whose solution does not exist for all data, or is not unique or does not depend uniquely on the data. In biomedical imaging this last feature has particularly deleterious consequences: indeed, the presence of measurement noise in the raw data may produce notable numerical instabilities in the reconstruction when naive approaches are applied.

Most (if not all) biomedical imaging problems are ill-posed inverse problems (Bertero & Boccacci, 1998) whose solution is a difficult mathematical task and often requires a notable computational effort. The first step toward the solution is represented by an accurate modeling of the mathematical relation between the biological organ to be imaged and the data provided by the imaging

device. Under the most general assumptions the model equation is a non-linear integral equation, although, for several devices, the non-linear imaging equation can be reliably approximated by a linear model where the integral kernel encodes the impulse response of the instrument. Such linearization can be either performed through a precise technological realization, like in MRI, where acquisition is designed in such a way that the data are just the Fourier Transform of the object to be imaged; or obtained mathematically, by applying a sort of perturbation theory to the non-linear equation, like in diffraction tomography whose model comes from the linearization of the scattering equation.

The second step toward image reconstruction is given by the formulation of computational methods for the reduction of the model equation. In the case of linear ill-posed inverse problems, a well-established **regularization** theory exists which attenuates the numerical instability related to ill-posedness maintaining the biological reliability of the reconstructed image. Regularization theory is at the basis of most linear imaging modalities and regularization methods can be formulated in both a probabilistic and a deterministic setting. Unfortunately an analogously well-established theory does not exist in the case of non-linear imaging problems which therefore are often addressed by means of 'ad hoc' techniques.

Once an image has been reconstructed from the data, a third step has to be considered, i.e. the processing of the reconstructed images for the extraction and interpretation of their information content. Three different problems are typically addressed at this stage:

- **Edge detection** (Trucco & Verri, 1998). Computer vision techniques are applied in order to enhance the regions of the image where the luminous intensity changes sharply.
- **Image integration** (Maintz & Viergever, 1998). In the clinical workflow several images of a patient are taken with different modalities and geometries. These images can be fused in an integrated model by recovering changes in their geometry.
- **Image segmentation** (Acton & Ray, 2007). Partial volume effects make the interfaces between the different tissues extremely fuzzy, thus complicating the clinical interpretation of the restored images. An automatic procedure for the partitioning of the image in homogeneous pixel sets and for

the classification of the segmented regions is at the basis of any Computed Aided Diagnosis and therapy (CAD) software.

AI algorithms and, above all, machine learning play a crucial role in addressing these image processing issues. In particular, as a subfield of machine learning, pattern recognition provides a sophisticated description of the data which, in medical imaging, allows to locate tumors and other pathologies, measure tissue dimensions, favor computer-aided surgery and study anatomical structures. For example, supervised approaches like backpropagation (Freeman & Skapura, 1991) or boosting (Shapire, 2003) accomplish classification tasks of the different tissues from the knowledge of previously interpreted images; while unsupervised methods like Self-Organizing Maps (SOM) (Kohonen, 2001), fuzzy clustering (De Oliveira & Pedrycz, 2007) and Expectation-Maximization (EM) (McLachlan & Krishnan, 1996) infer probabilistic information or identify clustering structures in sets of unlabeled images. From a mathematical viewpoint, several of these methods correspond more to heuristic recipes than to rigorously formulated and motivated procedures. However, since the last decade the theory of **statistical learning** (Vapnik, 1998) has appeared as the best candidate for a rigorous description of machine learning within a functional analysis framework.

FUTURE TRENDS

Among the main goals of recent biomedical imaging we point out the realization of

- microimaging techniques which allow the investigation of biological tissues of micrometric size for both diagnostic and research purposes;
- hybrid systems combining information from different modalities, possibly anatomical and functional;
- highly non-invasive diagnostic tools, where even a modest discomfort is avoided.

These goals can be accomplished only by means of an effective interplaying of hardware development and application of innovative image processing algorithms. For example, microtomography for biological samples requires the introduction of both new X-ray

tubes for data acquisition and computational methods for the reduction of beam hardening effects; electrophysiological and structural information on the brain can be collected by performing an EEG recording inside an MRI scanning but also using the structural information from MRI as a prior information in the analysis of the EEG signal accomplished in a Bayesian setting; finally, non-invasivity in colonoscopy can be obtained by utilizing the most recent acquisition design in X-ray tomography together with sophisticated softwares which allow virtual navigation within the bowel, electronic cleansing and automatic classification of cancerous and healthy tissues.

From a purely computational viewpoint, two important goals in machine learning applied to medical imaging are the development of algorithms for semi-supervised learning and for the automatic integration of genetic data with information coming from the acquired imagery.

CONCLUSION

Some aspects of recent biomedical imaging have been described from a computational science perspective. The biomedical image reconstruction problem has been discussed as an ill-posed inverse problem where the intrinsic numerical instability producing image artifacts can be reduced by applying sophisticated regularization methods. The role of image processing based on machine learning techniques has been described together with the main goals of recent biomedical imaging applications.

KEY TERMS

Computer Aided Diagnosis (CAD): The use of computers for the interpretation of medical images. Automatic segmentation is one of the crucial task of any CAD product.

Edge Detection: Image processing technique for enhancing the points of an image at which the luminous intensity changes sharply.

Electroencephalography (EEG): Non-invasive diagnostic tool which records the cerebral electrical activity by means of surface electrodes placed on the skull.

Ill-Posedness: Mathematical pathology of differential or integral problems, whereby the solution of the problem does not exist for all data, or is not unique or does not depend continuously on the data. In computation, the numerical effects of ill-posedness are reduced by means of regularization methods.

Image Integration: In medical imaging, combination of different images of the same patient acquired with different modalities and/or according to different geometries.

Magnetic Resonance Imaging (MRI): Imaging modality based on the principles of nuclear magnetic resonance (NMR), a spectroscopic technique used to obtain microscopic chemical and physical information about molecules. MRI can be applied in both functional and anatomical settings.

Magnetoencephalography (MEG): Non-invasive diagnostic tool which records the cerebral magnetic activity by means of superconducting sensors placed on a helmet surrounding the brain.

Segmentation: Image processing technique for distinguishing the different homogeneous regions in an image.

Statistical Learning: Mathematical framework which utilizes functional analysis and optimization tools for studying the problem of inference.

Tomography: Imaging technique providing two-dimensional views of an object. The method is used in many disciplines and may utilize input radiation of different nature and wavelength. There exist X-ray, optical, microwave, diffraction and electrical impedance tomographies.

Computer Morphogenesis in Self-Organizing Structures

Enrique Fernández-Blanco

University of A Coruña, Spain

Julián Dorado de la Calle

University of A Coruña, Spain

INTRODUCTION

Applying biological concepts to create new models in the computational field is not a revolutionary idea: science has already been the basis for the famous artificial neuron models, the genetic algorithms, etc. The cells of a biological organism are able to compose very complex structures from a unique cell, the zygote, with no need for centralized control (Watson J.D. & Crick F. H. 1953). The cells can perform such process thanks to the existence of a general plan, encoded in the DNA for the development and functioning of the system. Another interesting characteristic of natural cells is that they form systems that are tolerant to partial failures: small errors do not induce a global collapse of the system. Finally, the tissues that are composed by biological cells present parallel information processing for the coordination of tissue functioning in each and every cell that composes this tissue.

All the above characteristics are very interesting from a computational viewpoint. This paper presents the development of a model that tries to emulate the biological cells and to take advantage of some of their characteristics by trying to adapt them to artificial cells. The model is based on a set of techniques known as *Artificial Embryology* (Stanley K. & Miikkulainen R. 2003) or *Embryology Computation* (Kumar S. & Bentley P.J 2003).

BACKGROUND

The Evolutionary Computation (EC) field has given rise to a set of models that are grouped under the name of Artificial Embryology (AE), first introduced by Stanley and Miikkulainen (Stanley K. & Miikkulainen R. 2003). This group refers to all the models that try to apply certain characteristics of biological embryonic cells to

computer problem solving, i.e. self-organisation, failure tolerance, and parallel information processing.

The work on AE has two points of view. On the one hand can be found the grammatical models based on L-systems (Lindenmayer A. 1968) which do a top-down approach to the problem. On the other hand can be found the chemical models based on the Turing's ideas (Turing A. 1952) which do a down-top approach.

On the last one, the starting point of this field can be found in the modelling of gene regulatory networks, performed by Kauffman in 1969 (Kauffman S.A. 1969). After that, several works were carried out on subjects such as the complex behaviour generated by the fact that the differential expression of certain genes has a cascade influence on the expressions of others (Mjolsness E., Sharp D.H., & Reinitz J. 1995).

The work performed by the scientific community can be divided into two main branches. The more theoretical branch uses the emulation of cell capabilities such as cellular differentiation and metabolism (Kitano H. 1994; Kaneko K. 2006) to create a model that functions as a natural cell. The purpose of this work is to do an in-depth study of the biological model.

The more practical branch mainly focuses on the development of a cell inspired-model that might be applicable to other problems (Bentley, P.J., Kumar, S. 1999; Kumar, S. 2004). According to this model, every cell would not only have genetic information that encodes the general performance of the system, it would also act as a processor that communicates with the other cells. This model is mainly applied to the solution of simple 3D spatial problems, robot control, generative encoding for the construction of artificial organisms in simulated physical environments and real robots, or to the development of the evolutionary design of hardware and circuits (Endo K., Maeno T. & Kitano H 2003; Tufte G. & Haddow P. C. 2005).

Considering the gene regulatory networks works, the most relevant models are the following: the Kumar and Bentley model (Kumar S. & Bentley P.J 2003), which uses the Bentley's theory of fractal proteins (Bentley, P.J. 1999); for the calculation of protein concentration; the Eggenberger model (Eggenberger P. 1996), which uses the concepts of cellular differentiation and cellular movement to determine cell connections; and the work of Dellaert and Beer (Dellaert F. & Beer R.D. 1996), who propose a model that incorporates the idea of biological operons to control the model expression, where the function assumes the mathematical meaning of a Boolean function.

All these models can be regarded as special cellular automata. In cellular automata, a starting cell set in a certain state will turn into a different set of cells in different states when the same transition function (Conway J.H. 1971) is applied to all the cells during a determined lapse of time in order to control the message concurrence among them. The best known example of cellular automata is Conway's "Game of Life", where this behaviour can be observed perfectly. Whereas the classical conception specifies the behaviour rules, the evolutionary models establish the rules by searching for a specific behaviour. This difference comes from the mathematical origin of the cellular automata, whereas the here presented models are based on biology and embryology.

These models should not be confused with other concepts that might seem similar, such as Gene Expression Programming (GEP) (Ferreira C. 2006). Although GEP codifies the solution in a string, similarly as how it is done in the present work, the solution program is developed in a tree shape, as in classical genetic programming (Koza, J. et. al. 1999) which has little or nothing in common with the presented models.

ARTIFICIAL EMBRYOGENY MODEL

The cells of a biological system are mainly determined by the DNA strand, the genes, and the proteins contained by the cytoplasm. The DNA is the structure that holds the gene-encoded information that is needed for the development of the system. The genes are activated or transcribed thanks to the protein shaped-information that exists in the cytoplasm, and consist of two main parts: the sequence, which identifies the protein that will be generated if the gene is transcribed, and the

promoter, which identifies the proteins that are needed for gene transcription.

Another remarkable aspect of biological genes is the difference between constitutive genes and regulating genes. The latter are transcribed only when the proteins identified in the promoter part are present. The constitutive genes are always transcribed, unless inhibited by the presence of the proteins identified in the promoter part, acting then as gene oppressors.

The present work has tried to partially model this structure with the aim of fitting some of its abilities into a computational model; in this way, the system would have a structure similar that is similar to the above and will be detailed in the next section.

Proposed Model

Various model variants were developed on the basis of biological concepts. The proposed artificial cellular system is based on the interaction of artificial cells by means of messages that are called proteins. These cells can divide themselves, die, or generate proteins that will act as messages for themselves as well as for neighbour cells.

The system is supposed to express a global behaviour towards the generation of structures in 2D. Such behaviour would emerge from the information encoded in a set of variables of the cell that, in analogy with the biological cells, will be named genes.

One promising application, in which we are working, could be the compact encoding of adaptive shapes, similar to the functioning of fractal growth or the fractal image compression.

Figure 1. Structure of a system gene

The central element of our model is the artificial cell. Every cell has a binary string-encoded information for the regulation of its functioning. Following the biological analogy, this string will be called DNA. The cell also has a structure for the storage and management of the proteins generated by the own cell and those received from neighbourhood cells; following the biological model, this structure is called cytoplasm.

The DNA of the artificial cell consists of functional units that are called genes. Each gene encodes a protein or message (produced by the gene). The structure of a gene has four parts (see **Figure 1**):

- **Sequence:** the binary string that corresponds to the protein that encodes the gene
- **Promoters:** is the gene area that indicates the proteins that are needed for the gene's transcription.
- **Constituent:** this bit identifies if the gene is constituent or regulating
- **Activation percentage (binary value):** the percentage of minimal concentration of promoters proteins inside the cell that causes the transcription of the gene.

The other fundamental element for keeping and managing the proteins that are received or produced by the artificial cell is the cytoplasm. The stored proteins have a certain life time before they are erased. The cytoplasm checks which and how many proteins are needed for the cell to activate the DNA genes, and as such responds to all the cellular requirements for the concentration of a given type of protein. The cytoplasm also extracts the proteins from the structure in case they are needed for a gene transcription.

Model Functioning

The functioning of genes is determined by their type, which can be constituent or regulating. The transcription of the encoded protein occurs when the promoters of the non-constituent genes appear in a certain rate at the cellular cytoplasm. On the other hand, the constituent genes are expressed during all the “cycles” until such expression is inhibited by the present rate of the promoter genes.

$$\text{Protein Concentration Percent} \geq \frac{1}{(\text{Distance} + 1) * \text{Activation Percent}} \quad (1)$$

The activation of the regulating genes or the inhibition of the constituent genes is achieved if the condition expressed by **Eq.1** is fulfilled, where *Protein Concentration Percentage* represents the cytoplasm concentration of the protein that is being considered; *Distance* stands for the Hamming distance between one promoter and the considered protein; and *Activation Percentage* is the minimal percentage needed for the gene activation that is encoded in the gene. This equation is tested on each promoter and each protein. If the condition is fulfilled for all the promoters, that gene is transcribed. According to this, if gene-like promoters exist in a concentration higher than the encoded concentration, they can also induce its transcription, similarly to what happens in biology and therefore providing the model with higher flexibility. If the condition is fulfilled for each promoter, the gene is activated and therefore transcribed.

After the activation of one of the genes, three things can happen: the generated protein may be stored in the cell cytoplasm, it may be communicated to the neighbour cells, or it may induce cellular division (mitosis) and/or death (apoptosis). The different events of a tissue are managed in the cellular model by means of “cellular cycles”. Such “cycles” will contain all the actions that can be carried out by the cells, restricting sometimes their occurrence. The “cellular cycles” can be described as follows:

- Actualisation of the life time of proteins in the cytoplasm
- Verification of the life status of the cell (cellular death)
- Calculation of the genes that react and perform the special behaviour that may be associated to them
- Communication between proteins

Solution Search

A classical approach of EC proposes the use of Genetic Algorithms (GA) (Fogel L.J., Owens A. J. & Walsh M.A. 1966; Goldberg D.E. 1989; Holland J.H. 1975) for the optimisation, in this case, of the values of the DNA genes (binary strands). Each individual of the GA population will represent a possible DNA strand for problem solving.

In order to calculate the fitness value for every individual in the GA or the DNA, the strand is introduced into an initial cell or zygote. After simulating during a

Figure 2. (Above) Three promoters and a PCS structure (Below); Example of GA genes association for the encoding of cellular genes

certain number of cycles, the contained information is expressed and the characteristics of the resulting tissue are evaluated by means of various criteria, according to the goal that is to be achieved.

The encoding of the individual genes follows a structure that is similar to the one described in **Figure 2 (Above)**, where the number of promoters of each gene may vary but the white and indivisible section “Activation Percentage – Constituent – Sequence” (PCS) must always be present. The PCS sections determine the genes of the individual, and the promoter sections are associated to the PCS sections, as shown in **Figure 2(Below)**.

The search of a set of structures similar to those shown in **Figure 2** required the adaptation of the crossover and mutation GA operations to this specific problem. Since the length of the individuals is variable, the crossover had to be performed according to these lengths. When an individual is selected, a random percentage is generated to determine the crossover point of that individual. After selecting the section in that position, a crossover point is chosen for the section selected in the other parent. Once this has been done, the crossover point selection process is repeated in the second selected parent in the same position as in the previous individual. From this stage on, the descendants are composed in the traditional way, since they are two strings of bits. We could execute a normal bit strings crossover, but the previously mentioned steps guarantee that the descendants are valid solutions for the DNA strands transformation.

With regards to mutation, it should be mentioned that the types of the promoter or PCS sections are identified according to the value of the first string bit. Bearing that in mind, together with the variable length of individuals, the mutation operation had to be adapted

so that it could modify not only the number of these sections, but also the value of a given section.

The probability of executing the mutation is usually low, but this time it even had to be divided into the three possible mutation operations that the system contemplates. Various tests proved that the most suitable values for the distribution of the different mutation operations, after the selection of a position for mutation, were the following: for 20% of the opportunities, a section (either a promoter or a PCS) is added; for another 20%, the existing section is removed; and finally, for the remaining 60% of the opportunities, the value of one of the bits of the section is randomly changed. The latter may provoke not only the change of one of the values, but also the change of the section type: if the bit that identifies the section type is changed, the information of that section varies. For instance, if a promoter section turns into a PCS section, the promoter sequence turns into the gene sequence, and constitutive and activation percentage values are generated.

After reaching this development level and presenting the test set in (Fernández-Blanco E., Dorado J., Rabuñal J.R., Gestal M. & Pedreira N. 2007), the authors concluded that the bottleneck of the model turned out to be the development of the evaluation functions, since in every new figure the development of the function was time-consuming and not reusable.

In order to solve this problem, the evaluation function was developed according to the concept of a correction template. From the tissue that is developed by the DNA that is being evaluated, the centroid is calculated. This point would be the center of the solution template, which is merely a matrix of Boolean values representing the figure that is aimed at. The template could be (and usually is) smaller than the development environment of the tissue, which means that every cell that may not be covered by the template will contribute to the tissue error with 1.0. The remaining tissue, covered by the

Figure 3. Tissue + Template. Example of Template use.

template, will execute the NEXOR Boolean operation in order to obtain the number of differences between the template and the tissue. Each difference contributes with a value of 1.0. to tissue error.

Figure 3 illustrates the use of this method. We can observe that the error of this tissue with regard to the template is 2, since we generated a cell that is not contemplated by the template, whereas another cell that is present in the template is really missing.

FUTURE TRENDS

The model could also include new characteristics such as the displacement of cells around their environment, or a specialisation operator that blocks pieces of DNA during the expression of its descendants, as happens in the natural model.

Finally, this group is currently working in one of the possible applications of this model: its use for image compression similarly as fractal compression works. The fractal compression searches the parameters of a fractal formula that encodes itself the starting image. The present model searches the gene sequence that might result in the starting image. In this way, the method based on template that has been presented in this paper can be used for performing that search, using the starting image as template.

CONCLUSION

Taking into account the here developed model, we can say that the use of certain properties of biological cellular systems is feasible for the creation of artificial structures that might be used in order to solve certain computational problems.

Some behaviours of the biological model have been also observed in the artificial model: information redundancy in DNA, stability after achieving the desired shape, or variability in gene behaviour.

KEY TERMS

Artificial Cell: Each of the elements that process the orders codified into the DNA.

Artificial Embryogeny: The term overlaps all the processing models which use biological development ideas as inspiration for its functioning.

Cellular Cycle: Cellular development time unit which limits the occurrence number of certain cellular development actions.

Cytoplasm: Part of an artificial cell which is responsible of managing the protein-shaped messages.

DNA: Set of rules which are responsible of the cell behaviour.

Gene: Each of the rules which codifies one action of the cell.

Protein: This term identifies every kind of the messages that receives an artificial cell.

Zygote: The initial cell from where a tissue is generated using the DNA information.

Computer Vision for Wave Flume Experiments

Óscar Ibáñez

University of A Coruña, Spain

Juan Ramón Rabuñal Dopico

University of A Coruña, Spain

INTRODUCTION

During the past several decades, a number of attempts have been made to contain oil slicks (or any surface contaminants) in the open sea by means of a floating barrier. Many of those attempts were not very successful especially in the presence of waves and currents. The relative capabilities of these booms have not been properly quantified for lack of standard analysis or testing procedure (Hudon, 1992). In this regard, more analysis and experimental programs to identify important boom effectiveness parameters are needed.

To achieve the desirable performance of floating booms in the open sea, it is necessary to investigate the static and dynamic responses of individual boom sections under the action of waves; this kind of test is usually carried out in a wave flume, where open sea conditions can be reproduced at a scale.

Traditional methods use capacitance or conductivity gauges (Hughes, 1993) to measure the waves. One of these gauges only provides the measurement at one point; further, it isn't able to detect the interphase between two or more fluids, such as water and a hydrocarbon. An additional drawback of conventional wave gauges is their cost.

Other experiments such as velocity measurements, sand concentration measurements, bed level measurements, breakwater's behaviour, etc... and the set of traditional methods or instruments used in those experiments which goes from EMF, ADV for velocity measurements to pressure sensors, capacity wires, acoustic sensors, echo soundings for measuring wave height and sand concentration, are common used in wave flume experiments. All instruments have an associate error (Van Rijn, Grasmeijer & Ruessink, 2000), and an associate cost (most of them are too expensive for a lot of laboratories that can not afford pay those amount of money), certain limitations and some of them need a large term of calibration.

This paper presents another possibility for wave flume experiments, computer vision, which used a cheap and affordable technology (common video cameras and pc's), it is calibrated automatically (once we have developed the calibration task), is a non-intrusive technology and its potential uses could takes up all kind experiments developed in wave flumes. Are artificial vision's programmers who can give computer vision systems all possibilities inside the visual field of a video camera. Most experiments conducted in wave flumes and new ones can be carried out programming computer vision systems. In fact, in this paper, a new kind of wave flume experiment is presented, a kind of experiment that without artificial vision technology it couldn't be done.

BACKGROUND

Wave flume experiments are highly sensitive to whatever perturbation; therefore, the use of non-invasive measurement methodologies is mandatory if meaningful measures are desired. In fact, theoretical and experimental efforts whose results have been proposed in the literature have been mainly conducted focusing on the equilibrium conditions of the system (Niederoda and Dalton, 1982), (Kawata and Tsuchiya, 1988).

In contrast with most traditional methods used in wave flume experiments computer vision systems are non-invasive ones since the camera is situated outside the tank and in addition provide better accuracy than most traditional instruments.

The present work is part of a European Commission research project, "Advanced tools to protect the Galician and Northern Portuguese coast against oil spills at sea", in which a number of measurements in a wave flume must be conducted, such as the instantaneous position of the water surface or the motions (Milgran, 1971) of a floating containment boom to achieve these

objectives, a non-intrusive method is necessary (due to the presence of objects inside the tank) and the method has to be able to differentiate between at least two different fluids, with the oil slick in view.

Others works using image analysis to measure surface wave profile, have been developed over the past ten years (e.g., Erikson and Hanson, 2005; García, Heranz, Negro, Varela & Flores, 2003; Javidi and Psaltis, 1999; Bonmarin, Rochefort & Bourguel, 1989; Zhang, 1996), but they were developed neither with a real-time approach nor as non-intrusive methods. In some of these techniques it is necessary to colour the water with a fluorescent dye (Erikson and Hanson, 2005), which is not convenient in most cases, and especially when two fluids must be used (Flores, Andreatta, Llona & Saavedra, 1998).

A FRAMEWORK FOR MEASURING WAVES LEVEL IN A WAVE FLUME WITH ARTIFICIAL VISION TECHNIQUES

Following is presented an artificial vision system (Ibáñez, Rabuñal, Castro, Dorado, Iglesias & Pazos, 2007) which obtains the free surface position in all points of the image, from which the wave heights can be computed. For this aim we have to record a wave tank (see laboratory set-up in section 2) while it is generating waves and currents (a scale work frame), and after that we have to use the frames which make up the image to obtain the crest of the water (using computer vision techniques described in section 3) and translate the distances in the image to real distances (taking into account image rectification, see section 1).

Image Rectification

Lens distortion is an optical error in the lens that causes differences in magnification of the object at different points on the image; straight lines in the real world may appear curved on the image plane (Tsai, 1987). Since each lens element is radially symmetric, and the elements are typically placed with high precision on the same optical axis, this distortion is almost always radially symmetric and is referred to as radial lens distortion (Ojanen, 1999). There are two kinds of lens distortion: barrel distortion and pincushion distortion. Most lenses exhibit both properties at different scales.

Figure 1. Template to image rectification. Crosses are equidistant with a 4cm separation.

To avoid lens distortion error and to provide a tool for transforming image distances (number of pixels) to real distances (mm) it is necessary to follow a rectification procedure.

Most image rectification procedures involve a two step process (Ojanen, 1991). (Holland, Holman & Salenger, 1991): calibration of intrinsic camera parameters, and correction for a camera's extrinsic parameters (i.e., the location and rotation in space).

However, in our case we are only interested in transforming pixel measurements into real distances (mm). Transforming points from a real world surface to a non-coplanar image plane would imply an operator which, when applied to all frames, would considerably slow down the total process, which is not appropriate for our real-time approach.

So a .NET routine was developed to create a map with the corresponding factor (between pixel and real distances) for each group of pixels (four nearest control points on the target). Inputs to the model are a photographed image of the target sheet (see fig.1), and target dimensions (spacing between control points in the x- and y-directions).

Laboratory Set-Up and Procedure

The experiment was conducted in a 17.29-m long wave flume at the Centre of Technological Innovation in

Figure 2. Laboratory set-up diagram

Construction and Civil Engineering (CITEEC), in the University of A Coruña, Spain. The flume section is 77 cm (height) x 59.6 cm (width). Wave generation is conducted by means of a piston-type paddle. A wave absorber is located near its end wall to prevent wave reflection. It consists of a perforated plate with a length of 3.04 m, which can be placed at different slopes. The experimental set-up is shown in fig. 2.

With the aim of validating the system, solitary waves were generated and measured on the base of images recorded by a video camera mounted laterally, which captured a flume length of 1 m. The waves were also measured with one conductivity wave gauge located within the flume area recorded by the video camera. These gauges provide an accuracy of ± 1 mm at a maximum sampling frequency of 30 Hz.

A video camera, Sony DCR-HC35E, was used in turn to record the waves; it worked on the PAL Western Europe standard, with a resolution of 720 x 576 pixels, recording 25 frames per second.

The camera was mounted on a standard tripod and positioned approximately 2 m from the sidewall of the tank (see fig. 2). It remained fixed throughout the duration of a test. The procedure is as follows:

- Place one mark on the glass sidewall of the flume, on the bottom of the filmed area (see fig. 2);
- Place a template with equidistant marks (crosses) in a vertical plane parallel to the flume sidewall (see fig 1).
- Position the camera at a distance from the target plane (i.e., tank sidewall) depending on desired resolution.

- Adjust the camera taking into account the template's marks.
- Provide uniform and frontal lighting for the template.
- Film the template.
- Provide uniform lighting on the target plane and a uniformly colored background on the opposite sidewall (to block any unwanted objects from the field of view);
- Start filming.

The mark was placed horizontally on the glass sidewall of the flume, on the bottom of the filmed area in order to know a real distance between the bed of the tank and this mark, to avoid filming the bed of the tank and thus to film a smaller area (leading to a better resolution).

With regard to the lighting of the laboratory it is necessary to avoid direct lighting and consequently we can work without gleam and glints.

To achieve this kind of lighting, all lights in the laboratory were turned off and two halogen lamps of 200W were placed on both sides of the filmed area, one in front the other (see fig. 2).

Video Image Post-Processing

Image capture was carried out on a PC, Pentium 4, 3.00 GHz and 1.00 GB de RAM memory with the Windows XP platform. Filmed with the Sony DCR-HC35E¹, a high-speed interface card, IEEE 1394 FireWireTM, was used to transfer digital data from the camcorder to the computer, and the still images were kept in the

uncompressed bitmap format so that information would not be lost. De-interlacing was not necessary because of the quality of the obtained images and everything was done on a real-time approach.

An automatic tool for measuring waves from consecutive images was developed. The tool was developed under .NET framework, using C++ language and OpenCV (Open Source Computer Vision Library, developed by Intel²) library. The computer vision procedure is as follows:

- Extract a frame from the video.
- Using different computer vision algorithms get the constant “pixel to mm” for each pixel.
- Using different computer vision algorithms, the crest of the wave is obtained.
- Work out the corresponding height, for all the pixels in the crest of the wave.
- Supply results.
- Repeat the process until the video finish.

With regard to get the constant “pixel to mm”, a template with equidistant marks (crosses) is placed right up the glass sidewall of the tank and is filmed. Then a C++ routine recognize de centre of the crosses.

Results

A comparison of data extracted from video images with data measured by conventional instruments was

done. The comparisons are not necessarily meant to validate the procedure as there are inherent errors with conventional instruments, as well; rather, the comparisons aim to justify the use of video images as an alternative method for measuring wave and profile change data.

Different isolated measurements with conductivity gauge were done at the same time the video camera was recording. Then results from both methods were compared.

The process followed to measure with conductivity gauge and the artificial vision system at the same time involves recognizing one point in x-axis (in the record video) where the gauge is situated (one color mark was pasted around the gauge to make easier this task) and after knowing the measure point of the gauge we create a file with the height of the wave in this x point for each image in the video. While the video-camera is recording one file with gauge measure is created. Once we have both measure files we have two determine manually the same time point in both files (due to the difficulty to initialize both systems at the same time). Now, we can compare both measurements.

A lot of tests were done with different wave parameters for wave period, wave height and using regular (sine form) and irregular waves. Test with waves between 40mm and 200mm of height were done.

Using the camera DCR-HC35E, figure 3 shows one example of a test done, where the used wave was an irregular one, with a maximum period of 1s and a

Figure 3. Temporal sequence of measurement by sensor and image analysis

maximum value for wave amplitude of 70mm, excellent results were obtained as it can be seen in figure 4, where both measurements (conductivity sensor and video analysis) are quite similar.

The correlation between sensor and video image analysis measurements has an associated mean square error of 0.9948.

In spite of these sources of error, after several tests, the average error between conductivity sensor measurements and video analysis is 0.8 mm with camera DCR-HC35E, a lot better compared with the 5 mm average error obtained in the best work done until this moment (Erikson and Hanson, 2005). But it isn't an indicative error because of the commented source of errors taken into account in this study, however the estimated real error from this video analysis system is 1 mm, that is to say, the equivalence between one pixel and a real distance, and in our case (with the commented video camera and distance from the tank) one pixel is equivalent to nearly 1mm. This error could be improvable with a camera which allows a better resolution or focusing a smaller area.

FUTURE TRENDS

This is the first part of a bigger system which is capable of measuring the motions of a containment boom section in the vertical axis and its slope angle (Kim, Muralidharan, Kee, Jonson, & Seymour, 1998). Furthermore the system would be capable of making a distinction between the water and a contaminant, and thus would identify the area occupied by each fluid.

Another challenge is to test this system in other work spaces with different light conditions (i.e., in a different wave flume).

CONCLUSION

An artificial vision system was developed for these targets because these systems are non-intrusive and can separate a lot of different objects or fluids (anything that a human eye can differentiate) in the image and a non-intrusive method is necessary.

Other interesting aspects that these systems provide are:

- Cheaper price than traditional systems of measurement.
- Easier and faster to calibrate.
- It is unnecessary to mount an infrastructure to know what happens at different points of the tank (only one camera instead of an array of sensors).
- As the system is a non-intrusive one, it doesn't distort the experiments and their measurements.
- Provide high accuracy.
- Finally, this system is an innovation idea of applying computer vision techniques to civil engineering area and specifically in ports and coasts field. No similar works have been developed.

KEY TERMS

Color Spaces: (Konstantinos & Anastasios, 2000) supply a method to specify, sort and handle colors. These representations match n-dimensional sorts of the color feelings (n-components vector). Colors are represented by means of points in these spaces. There are lots of colors spaces and all of them start from the same concept, the Tri-chromatic theory of primary colors, red, green and blue.

Dilation: The dilation of an image by a structuring element ‘Y’ is defined as the maximum value of all the pixels situated under the structuring element

$$\varepsilon_Y(f)(x, y) = \min_{(s, t) \in Y} f(x + s, y + t).$$

The basic effect of this morphological operator the operator on a binary image is to gradually enlarge the boundaries of regions of foreground pixels (i.e. white pixels, typically). Thus areas of foreground pixels

grow in size while holes within those regions become smaller.

Erosion: The basic effect of the operator on a binary image is to reduce the definition of the objects. The erosion in the point (x,y) is the minimum value of all the points situated under the window, which is defined by the structuring element 'Y' that travels around the image:

$$\varepsilon_Y(f)(x,y) = \max_{(s,t) \in Y} f(x+s, y+t).$$

Harris Corner Detector: A popular interest point detector (Harris and Stephens, 1988) due to its strong invariance to (Schmid, Mohr, & Bauckhage, 2000): rotation, scale, illumination variation and image noise. The Harris corner detector is based on the local auto-correlation function of a signal; where the local auto-correlation function measures the local changes of the signal with patches shifted by a small amount in different directions.

Image Moments: (Hu, 1963; Mukundan and Ramakrishnan, 1998) they are certain particular weighted averages (moments) of the image pixels' intensities,

or functions of those moments, usually chosen to have some attractive property or interpretation. They are useful to describe objects after segmentation. Simple properties of the image which are found via image moments include area (or total intensity), its centroid, and information about its orientation.

Morphological Operators: (Haralick and Shapiro, 1992; Vernon, 1991) Mathematical morphology is a set-theoretical approach to multi-dimensional digital signal or image analysis, based on shape. The signals are locally compared with so-called structuring elements of arbitrary shape with a reference point.

Videometrics: (Tsai, 1987) can loosely be defined as the use of imaging technology to perform precise and reliable measurements of the environment.

INTRODUCTION

Survival analysis is used when we wish to study the occurrence of some event in a population of subjects and the time until the event of interest. This time is called *survival time* or *failure time*. Survival analysis is often used in industrial life-testing experiments and in clinical follow-up studies. Examples of application include: time until failure of a light bulb, time until occurrence of an anomaly in an electronic circuit, time until relapse of cancer, time until pregnancy.

In the literature we find many different modeling approaches to survival analysis. Conventional parametric models may involve too strict assumptions on the distributions of failure times and on the form of the influence of the system features on the survival time, assumptions which usually extremely simplify the experimental evidence, particularly in the case of medical data (Cox & Oakes, 1984). In contrast, semi-parametric models do not make assumptions on the distributions of failures, but instead make assumptions on how the system features influence the survival time (the usual assumption is the proportionality of hazards); furthermore, these models do not usually allow for direct estimation of survival times. Finally, non-parametric models usually only allow for a qualitative description of the data on the population level.

Neural networks have recently been used for survival analysis; for a survey on the current use of neural networks, and some previous attempts at neural network

survival modeling we refer to (Bakker & Heskes, 1999), (Biganzoli et al., 1998), (Eleuteri et al., 2003), (Lisboa et al., 2003), (Neal, 2001), (Ripley & Ripley, 1998), (Schwarzer et al. 2000).

Neural networks provide efficient parametric estimates of survival functions, and, in principle, the capability to give personalised survival predictions. In a medical context, such information is valuable both to clinicians and patients. It helps clinicians to choose appropriate treatment and plan follow-up efficiently. Patients at high risk could be followed up more frequently than those at lower risk in order to channel valuable resources to those who need them most. For patients, obtaining information about their prognosis is also extremely valuable in terms of planning their lives and providing care for their dependents.

In this article we describe a novel neural network model aimed at solving the survival analysis problem in a continuous time setting; we provide details about the Bayesian approach to modeling, and a sample application on real data is shown.

BACKGROUND

Let T denote an absolutely continuous positive random variable, with distribution function P , representing the time of occurrence of an event. The survival function, $S(t)$, is defined as:

$$S(t) = \Pr(T > t),$$

that is, the probability of surviving beyond time t . We shall generally assume that the survival function also depends on a set of covariates, represented by the vector x (which can itself be assumed to be a random variable). An important function related to the survival function is the *hazard rate* (Cox & Oakes, 1984), defined as:

$$h_r(t) = P'(t)/S(t)$$

where P' is the density associated to P . The hazard rate can be interpreted as the instantaneous force of mortality.

In many survival analysis applications we do not directly observe realisations of the random variable T ; therefore we must deal with a missing data problem. The most common form of missingness is *right censoring*, i.e., we observe realisations of the random variable:

$$Z = \min(T, C),$$

where C is a random variable whose distribution is usually unknown. We shall use a censoring indicator d to denote whether we have observed an event ($d=1$) or not ($d=0$). It can be shown that inference does not depend on the distribution of C (Cox & Oakes, 1984).

With the above definitions in mind we can now formulate the log-likelihood function necessary for statistical inference. We shall omit the details, and only report the analytical form:

$$L = \sum_i d_i \log h_r(t_i, x_i) - \int_0^{t_i} h_r(u, x_i) du.$$

For further details, we refer the reader to (Cox & Oakes, 1984).

CONDITIONAL HAZARD ESTIMATING NEURAL NETWORKS

Neural Network Model

The neural network model we used is the Multi-Layer Perceptron (MLP) (Bishop, 1995):

$$a(t, x; w) = b_0 + \sum_k v_k g(u_k^T x + u_0 t + b_k)$$

where $g()$ is a sigmoid function, and $w = \{b_0, v, u, u_0, b\}$ is the set of network parameters. The MLP output defines an analytical model for the logarithm of the hazard rate function:

$$a(t, x; w) \triangleq \log h_r(t, x)$$

We refer to this continuous time model as Conditional Hazard Estimating Neural Network (CHENN).

Bayesian Learning of the Network Parameters

The Bayesian learning framework offers several advantages over maximum likelihood methods commonly used in neural network learning (Bishop, 1995), (MacKay, 1992), among which the most important are automatic regularization and estimation of error bars on predictions.

In the conventional maximum likelihood approach to training, a single weight vector is found, which minimizes the error function; in contrast, the Bayesian scheme considers a probability distribution over weights w . This is described by a prior distribution $p(w)$ which is modified when we observe a dataset D . This process can be expressed by Bayes' theorem:

$$p(w | D) = \frac{p(D | w) p(w)}{p(D)}.$$

To evaluate the posterior distribution, we need expressions for the likelihood $p(D | w)$ (which we have already shown) and for the prior $p(w)$.

The prior over weights should reflect the knowledge, if any, we have about the mapping we want to build. In our case, we expect the function to be very smooth, so an appropriate prior might be:

$$p(w) \propto \exp\left(-\frac{1}{2} \sum_k \alpha_k w_k^T w_k\right)$$

which is a multivariate normal density with zero mean and diagonal covariance matrix with elements $1/\alpha_k$. In this way, weights centered on zero have higher probability, a fact which encourages very smooth functions.

Note that the prior is parametric, and the regularization parameters α_k (which are inverse variances) are called *hyperparameters*, because they control the distribution of the network parameters.

Note also that the prior is specialized for different groups of weights by using different regularization parameters for each group; this is done to preserve the scaling properties of network mappings (Bishop, 1995), (MacKay, 1992). This prior is called Automatic Relevance Determination (ARD). This scheme defines a model whose prior over the parameters embodies the concept of relevance, so that the model is effectively able to infer which parameters are relevant based on the training data and then switch the others off (or at least reduce their influence on the overall mapping).

The ARD modeling scheme in the case of the CHENN model defines weight groups for the inputs, the output layer weights, and the biases.

Once the expressions for the prior and the noise model are given, we can evaluate the posterior:

$$p(w|D) = \frac{1}{Z} \exp\left(L - \frac{1}{2} \sum_k \alpha_k w_k^T w_k\right).$$

This distribution is usually very complex and multimodal (reflecting the nature of the underlying error function, the term $-L$); and the determination of the normalization factor (also called the *evidence*) is very difficult. Furthermore, the hyperparameters must be integrated out, since they are only used to determine the form of the distributions.

A solution is to integrate out the parameters separately from the hyperparameters, by making a Gaussian approximation; then, searching for the mode with respect to the hyperparameters (Bishop, 1995), (MacKay, 1992). This procedure gives a good estimation of the *probability mass* attached to the posterior, in particular for distributions over high-dimensional spaces, which is the case for large networks.

The Gaussian approximation is in practice derived by finding a maximum of the posterior distribution, and then evaluating the curvature of the distribution around the maximum:

$$w_{MP} = \arg \max_w L - \frac{1}{2} \sum_k \alpha_k w_k^T w_k,$$

$$A = \nabla \nabla_w \left[-L + \frac{1}{2} \sum_k \alpha_k w_k^T w_k \right]_{w=w_{MP}}.$$

The approximation thus is:

$$p(w|D) \approx \frac{1}{Z_{MP}} \exp\left(-\frac{1}{2} (w - w_{MP})^T A^{-1} (w - w_{MP})\right)$$

where the normalisation constant is simply evaluated from usual multivariate normal formulas.

The hyperparameters are calculated by finding the maximum of the approximate *evidence* Z_{MP} . Alternate maximization (by using a nonlinear optimization algorithm) of the posterior and evidence is repeated until a self consistent solution $\{w_{MP}, \alpha_k\}$ is found.

The full Bayesian treatment of inference implies that we do not simply get a pointwise prediction for functions $f(x, t; w)$ of a model output, but a full distribution. Such predictive distributions have the form:

$$p(f(x, t | D)) = \int f(x, t | w) p(w | D) dw.$$

The above integrals are in general not analytically tractable, even when the posterior distribution over the parameters is Gaussian. However, it is usually enough to find the moments of the predictive distribution, in particular its mean and variance. A useful approximation is given by the delta method. Let $f(w)$ be the function (of w) we wish to approximate. By Taylor expanding to first order around w_{MP} we can write:

$$f(w) \approx f(w_{MP}) + (w - w_{MP})^T \nabla_w f(w)_{w=w_{MP}}.$$

Since this is a linear function of w , it will still be normally distributed under the Gaussian posterior, with mean and variance:

$$\mathbf{E}[f(w)] = f(w_{MP})$$

$$\mathbf{Var}[f(w)] = \nabla_w^T f A^{-1} \nabla_w f.$$

Error bars are simply obtained by taking the square root of the variance. We emphasize that it is important to evaluate first and second order information to understand the overall *quality* and *reliability* of a model's predictions. Error bars also provide hints on the distribution of the patterns (Williams et al., 1995) and can therefore be useful to understand whether a model is extrapolating its predictions. Furthermore, they can offer suggestions for the collection of future data (Williams et al., 1995; MacKay, 1992).

A Case Study: Ocular Melanoma

We show now an application of the CHENN model to the prognosis of all-cause mortality in ocular melanoma.

Intraocular melanoma occurs in a pigmented tissue called the uvea, with more than 90% of tumours involving the choroid, beneath the retina. About 50% of patients die of metastatic disease, which usually involves the liver.

Estimates for survival after treatment of uveal melanoma are mostly derived and reported using Cox analysis and Kaplan-Meier (KM) survival curves (Cox & Oakes). As a semiparametric model, the Cox method, however, usually utilizes linear relationships between variables, and the proportionality of risks is always assumed. It is therefore worth exploring the capability of nonlinear models, which do not make any assumptions about the proportionality of risks.

The data used to test the model were selected from the database of the Liverpool Ocular Oncology Centre (Taktak et al., 2004). The dataset was split into two parts, one for training (1823 patterns), the other one for test (781 patterns). Nine prognostic factors were used: Sex, Tumour margin, Largest Ultrasound Basal Diameter, Extraocular extension, Presence of epithelioid cells, Presence of closed loops, Mitotic rate, Monosomy of chromosome 3.

The performance of survival analysis models can in general be assessed according to their discrimination and calibration aspects. Discrimination is the ability of the model to separate correctly the subjects into different groups. Calibration is the degree of correspondence between the estimated probability produced by the model and the actual observed probability (Dreiseitl & Ohno-Machado, 2002). One of the most widely used methods for assessing discrimination in survival analysis is Harrell's C index (Dreiseitl & Ohno-Machado, 2002), (Harrell et al. 1982), an extension to survival analysis of the Area Under the Receiver Operator Characteristic (AUROC). Calibration is assessed by a Kolmogorov-Smirnov (KS) goodness-of-fit test with corrections for censoring (Kozioł, 1980).

The C index was evaluated for a set of years that are of interest to applications, from 1 to 7. The minimum was achieved at 7 years (0.75), the maximum at 1 year (0.8). The KS test with corrections for censoring was applied for the above set of years, and up to the maximum uncensored time (16.8 years); the confidence level was set as usual at 0.05. The null hypothesis that

the modeled distributions follow the empirical estimate cannot be rejected for years 1 to 7, whereas it is rejected if we compare the distributions up to 16.8 years; the null hypothesis is always rejected for the Cox model.

FUTURE TRENDS

Neural networks are very flexible modelling tools, and in the context of survival analysis they can offer advantages with respect to the (usually linear) modelling approaches commonly found in literature. This flexibility, however, comes at a cost: computational time and difficulty of interpretation of the model. The first aspect is due to the typically large number of parameters which characterise moderately complex networks, and the fact that the learning process results in a nonconvex, nonlinear optimization problem.

The second aspect is in some way a result of the nonlinearity and nonconvexity of the model. Addressing the issue of nonconvexity may be the first step to obtain models which can be easily interpreted in terms of their parameters, and easier to train; and in this respect, kernel machines (like Support Vector Machines) might be considered as the next step in flexible nonlinear modelling, although the formulation of learning algorithms for these models follows a paradigm which is not based on likelihood functions, and therefore their application to survival data is not immediate.

CONCLUSION

This article proposes a new neural network model for survival analysis in a continuous time setting, which approximates the logarithm of the hazard rate function. The model formulation allows an easy derivation of error bars on both hazard rate and survival predictions. The model is trained in the Bayesian framework to increase its robustness and to reduce the risk of overfitting. The model has been tested on real data, to predict survival from intraocular melanoma.

Formal discrimination and calibration tests have been performed, and the model shows good performance within a time horizon of 7 years, which is found useful for the application at hand.

KEY TERMS

Bayesian Inference: Inference rules which are based on application of Bayes' theorem and the basic laws of probability calculus.

Censoring: Mechanism which precludes observation of an event. A form of missing data.

Hyperparameter: Parameter in a hierarchical problem formulation. In Bayesian inference, the parameters of a prior.

Neural Networks: A graphical representation of a nonlinear function. Usually represented as a directed acyclic graph. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Posterior Distribution: Probabilistic representation of knowledge, resulting from combination of prior knowledge and observation of data.

Prior Distribution: Probabilistic representation of prior knowledge.

Random Variable: Measurable function from a sample space to the measurable space of possible values of the variable.

Survival Analysis: Statistical analysis of data represented in terms of realisation of point events. In medical applications usually the point event is the death of an individual, or recurrence of a disease.

Configuration

Luca Anselma

Diego Magro

Università di Torino, Italy

INTRODUCTION

Configuring means selecting and bringing together a set of given components to produce an aggregate (or a set of aggregates) satisfying some requirements. All the component types are predefined and no new component type may be created during the configuration process.

The result of the configuration can be physical objects (such as cars or elevators), non-physical entities (such as compound services or processes) or heterogeneous wholes made of both physical and non-physical parts (such as computer systems with their hardware and software components).

The configuration process has to take into consideration both endogenous and exogenous constraints: the former pertain to the type of the assembled object(s) (therefore they hold for all the individuals of that type) and mainly come from the interactions among components, whereas the latter usually represent requirements that the final aggregate(s) should satisfy. All these constraints can be very complex and make the manual solution of configuration problems a very hard task in many cases.

The complexity of configuration and its relevance in several application domains have stimulated the interest in its automation. Since the beginning, Artificial Intelligence has provided various effective techniques to achieve this goal. One of the first configurators was also one of the first commercially successful expert systems: a production rule-based system called *R1* (McDermott, 1982, 1993). *R1* was developed in the early Eighties to configure VAX computer systems, and it has been used for several years by Digital Equipment Corporation.

Since then, configuration has gained importance both in industry and in marketing, also due to both the support that it offers to the mass customization business strategy and the new commercial opportunities

provided by the Web. Configuration is currently an important application field for many Artificial Intelligence techniques and it is still posing many interesting problems to scientific research.

BACKGROUND

The increasing complexity and size of configurable products made it clear that production-rule-based configurators such as *R1* are not effective, particularly in the phase of maintenance of knowledge bases. In fact, changing a rule may require, as a side effect, changing several other rules and so on, and, actually, for some products, the component library may change frequently.

To partly address this problem, in current configurator systems, domain knowledge and control knowledge for problem solving are separate. The domain knowledge is represented in a declarative language, and the control knowledge (i.e., inferential mechanisms) is general (i.e., not depending on the particular problem to be solved). This is a common approach in modern knowledge-based systems. A configurator is based on an explicit representation of the general model of the configurable entities, which implicitly represents all the valid product individuals. The reasoning mechanisms implement the control knowledge and they use the domain knowledge to draw inferences and to compute configurations.

Regarding domain knowledge, there is a general agreement about what the concepts to represent are. In (Soininen, Tiuhonen, Männistö & Sulonen, 1998) the authors introduce a widely accepted **conceptualization** for configuration problems. This conceptualization includes the concepts of

- *components*, which are the constituents of configurations;

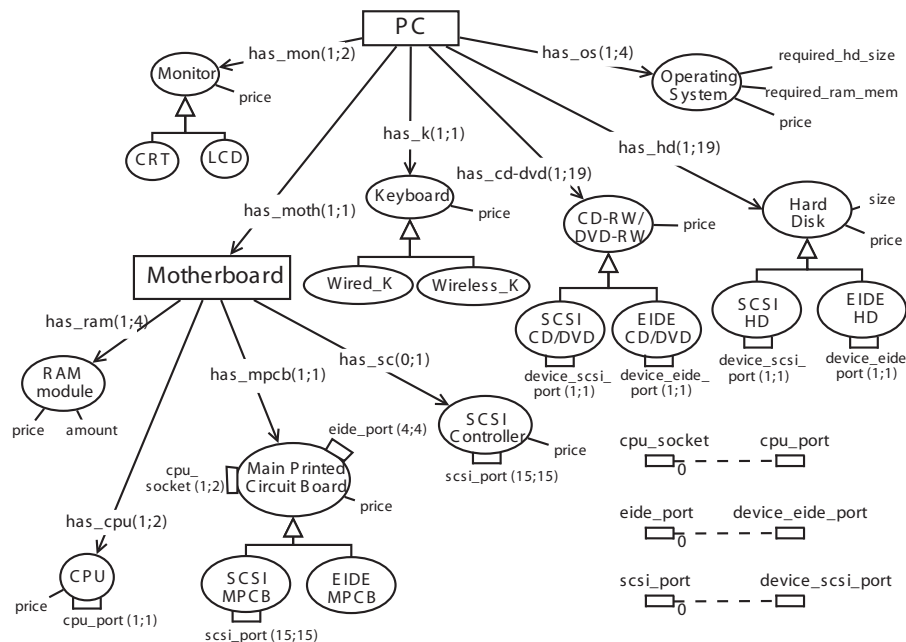

Configuration

- *parts* to describe the compositional structure;
- *ports* to model connections and compatibilities between components;
- *resources* that are produced, used or consumed by components;
- *functions* to represent functionalities;
- *attributes* used to describe components, ports, resources and functions;

- *taxonomies* in which component, port, resource and function types may be organized in;
- *constraints* to specify conditions that configurations must satisfy.

Figure 1 depicts a simplified fragment of the domain knowledge for PC configuration. It describes all the PC variants valid for the domain. Has-part relations

Figure 1. A fragment of a PC configuration knowledge base

Constraints

- In any PC, if there is any SCSI device, then there must be either a SCSI Main Printed Circuit Board or a SCSI Controller
- In any PC, there must be no more than four EIDE devices and no more than fifteen SCSI devices
- In any PC, the total hard disk space required by all the Operating Systems must be less than the size of hard disks
- In any PC, the RAM required by each Operating System must be less than the available RAM amount
- In any Motherboard, there cannot be both a SCSI Main Printed Circuit Board and a SCSI Controller
- ...

model the compositional structure of PCs (e.g., each PC has one or two monitors, a motherboard, etc.). Each component of a PC can be either of a basic (non configurable) type (e.g., the monitor) or of an aggregate (possibly configurable) type (e.g., the motherboard). Some relevant taxonomic relations are reported (e.g., the hard disks are either SCSI or EIDE). The basic components can be connected through ports (only few ports are reported): each port connects with at most one other port; for some ports the connection is

optional (e.g., for `eide_port`), for others it is mandatory (e.g., for `device_eide_port`). Some attributes (e.g., the price) describe the components. A set of constraints model the interactions among the components: e.g., the third constraint specifies that hard disks must provide enough space, which is a resource consumed by operating systems.

Figure 3 describes a particular PC variant, meeting the requirements stated in Figure 2 (containing also an optimization criterion on price).

Figure 2. An example of user requirements for a PC

Requirements

- The PC should have:
- two SCSI Hard Disks and at least 160 GB of Hard Disk
 - at least 1 GB RAM
 - a Wireless Keyboard
 - the cheapest price
 - ...

Figure 3. A configured PC, compliant with the domain knowledge in Figure 1 and meeting the requirements in Figure 2

AUTOMATIC CONFIGURATION

Despite the consensus over the conceptualization of the problem, there is a wide range of approaches to configuration, with reference to different paradigms of Artificial Intelligence. It is possible to identify two mainstreams in current approaches to configuration: namely, constraint-based frameworks and logic-based frameworks. Constraint-based frameworks emphasize combinatorial aspects of configuration problems which have large search spaces and few solutions, while logic-based frameworks, in general, stress the description of the compositional structure of the product.

As regards *constraint-based frameworks*, approaches based on Constraint Satisfaction Problem (CSP) (Dechter, 2003) and its extensions are widely adopted. In particular, the classical CSP paradigm has been extended to overcome some of its limitations. In fact, on the one hand, in classical CSP, the set of variables is fixed and they will all be assigned values in every solution. On the other hand, in the configuration task the number and the types of the components that will be part of the final valid configuration are usually not known in advance, since they are selected by the configurator during the configuration process.

This fact motivated the introduction of Dynamic CSP (DCSP) (Mittal & Falkenhainer, 1990) (Gelle & Sabin, 2006) (also known as Conditional CSP) paradigm. A DCSP is defined – as classical CSP – on a fixed set of variables, but – differently from classical CSP – during the problem solving phase, it only takes into account the subset of variables relevant to the solution (i.e., the active variables). DCSP formalizes the notion of a particular type of constraint, i.e., activity constraints, which can add or remove variables from a potential solution depending on conditions imposed on already active variables. The search process starts with an initial set of active variables, and additional variables are introduced (or explicitly left out) as search progresses, depending on satisfied activity constraints.

A generalization of the original DCSP proposal, as well as some results on complexity and expressiveness, are presented in (Soininen, Gelle & Niemelä, 1999). Several solving methods for DCSP are described and discussed in (Gelle & Sabin, 2003).

In (Stumptner & Haselböck, 1993) the authors further extend DCSP by introducing the Generative CSP. In Generative CSP the types of the components may be compactly described and managed; moreover,

generic constraints are defined: these are constraint schemata which can be instantiated on the specific variables activated at a particular point in the configuration process.

In (Sabin & Freuder, 1996) the authors overcome a second major limitation of CSP with regard to configuration problems: in fact, CSP is “flat”, i.e., it does not allow to represent the structure of a configuration product in a straightforward way. To overcome this limitation, Sabin and Freuder propose Composite CSP, an extension to CSP which allows one to take into account not only changing sets of components, but also the hierarchical structure of the final configurations. In Composite CSP variables take not only atomic values but also values representing entire subproblems. Whenever a variable is assigned with a subproblem value, the subproblem is “expanded” and the problem is dynamically modified: specifically, it is “refined” by considering also the variables and the constraints in the subproblem. In such a way, it is easy to adapt the CSP’s inferential mechanisms to Composite CSP.

Also classical CSP itself plays an important role in configuration. In fact, in (Aldanondo, Moynard & Hamou, 2000) an approach is presented that uses standard CSP techniques to solve configuration problems. Moreover, several results in the configuration research field somehow refer to standard CSP framework. For example, in (Freuder, Likitvivatanavong & Wallace, 2001) the authors explore the problem of generating explanations for configuration problems expressed as CSP. In (Freuder & O’Sullivan, 2001) the authors propose an approach for dealing with configuration problems expressed as CSP where it is not possible to satisfy all user requirements at the same time, and it is necessary to establish a satisfactory trade-off between them. (Amilhastre, Fargier & Marquis, 2002) extends CSP to offer support for interactive problem solving as in the case of interactive product configuration, where the interactivity refers to the user making choices during the configuration process. Specifically, the approach provides the user with features such as consistency maintenance (i.e., inconsistencies are discovered as soon as possible), consistency restoration (i.e., guidance for relaxing inconsistent choices) and explanations (i.e., minimal sets of inconsistent choices are identified). Finally, (Freuder, Carchrae & Beck, 2003) describes an approach for removing values of variables in a CSP that would lead to a dead-end in solving the CSP.

As regards *logic-based frameworks*, (McGuinness, 2002) analyzes Description Logics (DL) (Baader, Calvanese, McGuinness, Nardi & Patel-Schneider, 2003) as a convenient modeling tool for configurable products. DL make possible a description of the configuration knowledge by means of expressive conceptual languages with a rigorous semantics, thus enhancing knowledge comprehensibility and facilitating knowledge re-use. Furthermore, the powerful inference mechanisms currently available can be exploited both off-line by the knowledge engineers and on-line by the configuration system. Moreover, the paper describes a commercial DL-based family of configurators developed by AT&T.

(Soininen, Niemelä, Tiihonen & Sulonen, 2000) describes an approach in which the domain knowledge is represented with a high-level language and then mapped to a set of weight constraint rules, a form of logic programs offering support for expressing choices and both cardinality and resource constraints. Configurations are computed by finding stable Herbrand models of such a logic program.

(Sinz, Kaiser & Küchlin, 2003) presents an approach particularly geared to industrial context (in fact, it has been developed to be used by DaimlerChrysler for the configuration of their Mercedes lines). In Sinz et al.'s approach the domain knowledge is expressed as formulae in propositional logic; then, it is validated by running a satisfiability checker, which can also provide explanations in case of failure. However, this work aims at validating the knowledge base, rather than solving configuration problems.

There are also *hybrid approaches* that reconcile constraint-based frameworks and logic-based frameworks. For example, both (Magro & Torasso, 2003) and (Junker & Mailharro, 2003) describe hybrid frameworks based on a logic-based description of the structure of the configurable product (taking inspiration from logical languages derived from frame-based languages such as the DL) and on a constraint-based description of the possible ways of interaction between components.

In (Junker & Mailharro, 2003) constructs of DL are translated into concepts of constraint programming in order to solve a configuration problem. On the contrary, (Magro & Torasso, 2003) adopts an inference mechanism specific for configuration, which, basically, searches for tree-structured models on finite domains

for conceptual descriptions, and adapts some constraint-propagation techniques to the logical framework.

In most formalizations, the configuration task is theoretically intractable (at least NP-hard, in the worst case) and in some cases the intractability does appear also in practice and solving configuration problems can require a huge amount of CPU time. There are several ways that can be explored to cope with these situations: providing the configurator with a set of domain-specific heuristics, defining general focusing mechanisms (Magro & Torasso, 2001), making use of compilation techniques (Sinz, 2002) (Narodytska & Walsh, 2006), re-using past solutions (Geneste & Ruet, 2002), defining techniques to decompose a problem into a set of simpler subproblems (Magro, Torasso & Anselma, 2002) (Anselma & Magro, 2003).

Configuration has a growing commercial market. In fact, several configurator systems have been developed and some commercial tools are currently available (e.g., ILOG (Junker & Mailharro, 2003), Koalog, OfferIt! (Bergenti, 2004), Oracle, SAP (Haag, 2005), TACTON (Orsvarn, 2005)).

Furthermore, some Web sites have been equipped with configuration capabilities to support customers in selecting a suitable product in a wide range of domains such as cars (e.g., Porsche, Renault, Volvo), bikes (e.g., Pro-M Bike Configurator) and computers (e.g., Dell, Cisco).

FUTURE TRENDS

Many current configuration approaches and software configuration systems concern the configuration of mechanical or electronic devices/products and are conceived in order to be employed by domain experts, such as production or sales engineers.

Nowadays, the scope of configuration is growing and the application of automatic configuration techniques to non-physical entities is gaining more and more importance. The configuration of software products and complex services built on simpler ones are two research areas and application domains that are currently attracting the attention of researchers.

The capability of producing understandable *explanations* for their choices or for the inconsistencies that they encounter and of suggesting *consistency restorations* are some needs that configuration systems share with many knowledge-based or expert systems. However,

the aim of making configuration systems profitably used by non-expert users too and the deployment of configurators on the Web all contribute to strengthen the importance of these issues.

Explanations and restorations are also related to the topic of *interactive configuration*, which is still posing some challenging problems to researchers. Indeed, besides these capabilities, interactive configuration requires also effective mechanisms to deal with incomplete and/or incremental requirements specification (and with their retraction) and it is also demanding in terms of efficiency of the algorithms.

Real-world configuration knowledge bases can be very large and they usually are continually modified during their life cycle. Some research efforts are currently devoted to define powerful techniques and to design and implement tools that support *knowledge acquisition*, *knowledge-base verification* and *maintenance*.

Furthermore, a closer integration of configuration into the business models and of configurators into enterprise software systems is an important goal for several companies (as well as for enterprise software providers).

Distributed configuration is another important topic, especially in an environment where a specific complex product/service is provided by different suppliers that have to cooperate in order to produce it.

Finally, it is worth mentioning the *reconfiguration* of existing systems, which is still mainly an open problem.

CONCLUSION

Configuration has been a prominent area of Artificial Intelligence since the early Eighties, when it started to arouse interest among researchers working in academia and industry.

This article provides a general overview of the area of configuration by introducing the problem of configuration, briefly presenting a general conceptualization of configuration tasks, and succinctly describing some representative proposals in literature to deal with configuration problems.

As we have illustrated, during the last few years several approaches involving configuration techniques have been successfully applied in order to deal with issues pertaining to a wide range of real-world applica-

tion domains, ranging from cars to computer systems, from software to travel plans.

Theoretical results achieved by the academic environment have found effective, tangible applications in industrial settings, thus contributing to the diffusion of both industrial and commercial configurators. Such applications—in their turn—gave rise to new challenges, engendering a significant cross-fertilization of ideas among researchers in academia and in industry.

KEY TERMS

Constraint Satisfaction Problem (CSP): A CSP is defined by a finite set of variables, where each variable is associated with a domain, and a set of constraints over a subset of variables, restricting the possible combinations of values that the variables in the subset may assume. A solution of a CSP is an assignment of a value to each variable that is consistent with the constraints.

Description Logics (DL): Logics that are designed to describe concepts and individuals in knowledge bases. They were initially developed to provide a precise semantics for the frame systems and the semantic net-

works. The typical inference for concepts is checking if a concept is more general than (i.e., subsumes) another one. The typical inference for individuals is checking if an individual is an instance of a concept. Many DL are fragments of first-order logic, while some of them go beyond first order.

Logic Program: A logic theory (possibly containing some extra-logic operators) that can be given a procedural meaning such that the process of checking if a formula is derivable in the theory can be viewed as a program execution.

Mass Customization: A business strategy that combines the mass production paradigm with product personalization. It is closely related to the modularity in product design. This design strategy makes it possible to adopt the mass production model for standard modules, facilitates the management of product families and variants and it leaves room for (various kinds and degrees of) personalization.

Production-Rule-Based System: A system where knowledge is represented by means of production rules. A production rule is a statement composed of conditions and actions. If data in working memory satisfy the conditions, the related actions can be executed, resulting in an update of the working memory.

Propositional Logic Formula Satisfiability: The task of checking whether it is possible to assign a truth value to every variable that occurs in a propositional formula, such that the truth value of the whole formula equals *true*.

Stable Herbrand Model: A minimal set of facts satisfying a logic program (theory). Each fact in the model is a variable-free atom whose arguments are terms exclusively built through function and constant symbols occurring in the program and whose predicate symbols occur in the program as well. Facts not appearing in the model are regarded as false.

Constraint Processing

Roman Barták

Charles University in Prague, Czech Republic

INTRODUCTION

Constraints appear in many areas of human endeavour starting from puzzles like crosswords (the words can only overlap at the same letter) and recently popular Sudoku (no number appears twice in a row) through everyday problems such as planning a meeting (the meeting room must accommodate all participants) till solving hard optimization problems for example in manufacturing scheduling (a job must finish before another job). Though all these problems look like being from completely different worlds, they all share a similar base – the task is to find values of decision variables, such as the start time of the job or the position of the number at a board, respecting given constraints. This problem is called a Constraint Satisfaction Problem (CSP).

Constraint processing emerged from AI research in 1970s (Montanary, 1974) when problems such as scene labelling were studied (Waltz, 1975). The goal of scene labelling was to recognize a type of line (and then a type of object) in the 2D picture of a 3D scene. The possible types were convex, concave, and occluding lines and the combination of types was restricted at junctions of lines to be physically feasible. This scene labelling problem is probably the first problem formalised as a CSP and some techniques developed for solving this problem, namely arc consistency, are still in the core of constraint processing. Systematic use of constraints in programming systems has started in 1980s when researchers identified a similarity between unification in logic programming and constraint satisfaction (Gallaire, 1985) (Jaffar & Lassez, 1987). Constraint Logic Programming was born. Today Constraint Programming is a separate subject independent of the underlying programming language, though constraint logic programming still plays a prominent role thanks to natural integration of constraints into a logic programming framework.

This article presents mainstream techniques for solving constraint satisfaction problems. These tech-

niques stay behind the existing constraint solvers and their understanding is important to exploit fully the available technology.

BACKGROUND

Constraint Satisfaction Problem is formally defined as a triple: a finite set of decision variables, a domain of possible values, and a finite set of constraints restricting possible combinations of values to be assigned to variables. Although the domain can be infinite, for example real numbers, frequently, a finite domain is assumed. Without loss of generality, the finite domain can be mapped to a set of integers which is the usual case in constraint solvers. This article covers finite domains only. In many problems, each variable has its own domain which is a subset of the domain from the problem definition. Such domain can be formally defined by a unary constraint. We already mentioned that constraints restrict possible combinations of values that the decision variables can take. Typically, the constraint is defined over a subset of variables, its scope, and it is specified either extensionally, as a set of value tuples satisfying the constraint, or intentionally, using a logical or arithmetical formula. This formula, for example $A < B$, then describes which value tuples satisfy the constraint. A small example of a CSP is $(\{A, B, C\}, \{1, 2, 3\}, \{A < B, B < C\})$.

The task of constraint processing is to instantiate each decision variable by a value from the domain in such a way that all constraints are satisfied. This instantiation is called a *feasible assignment*. Clearly, the problem whether there exists a feasible assignment for a CSP is NP-complete – problems like 3SAT or knapsack problem (Garey & Johnson, 1979) can be directly encoded as CSPs. Sometimes, the core constraint satisfaction problem is accompanied by a so called objective function defined over (some) decision variables and we get a *Constrained Optimisation Problem*. Then the task is to select among the feasible assignments the assign-

ment that minimizes (or maximizes) the value of the objective function. This article focuses on techniques for finding a feasible assignment but these techniques can be naturally extended to optimization problems via a well-known branch-and-bound technique (Van Hentenryck, 1989).

There are several comprehensive sources of information about constraint satisfaction starting from journal surveys (Kumar, 1992) (Jaffar & Maher, 1996) through on-line tutorials (Barták, 1998) till several books. Van Hentenryck's book (1989) was a pioneering work showing constraint satisfaction in the context of logic programming. Later Tsang's book (1993) focuses on constraint satisfaction techniques independently of the programming framework and it provides full technical details of most algorithms described later in this article. Recent books cover both theoretical (Apt, 2003) and practical aspects (Marriott & Stuckey, 1998), provide good teaching material (Dechter, 2003) or in-depth surveys of individual topics (Rossi *et al.*, 2006). We should not forget about books showing how constraint satisfaction technology is applied in particular areas; scheduling problems play a prominent role here (Baptiste *et al.*, 2001) because constraint processing is exceptionally successful in this area.

CONSTRAINT SATISFACTION TECHNIQUES

Constraint satisfaction problems over finite domains are basically combinatorial problems so they can be solved by exploring the space of possible (partial or complete) instantiations of decision variables. Later in this section we will present the typical search algorithms used in constraint processing. However, it should be highlighted that constraint processing is not simple enumeration and we will also show how so called consistency techniques contribute to solving CSPs.

Systematic Search

Search is a core technology of artificial intelligence and many search algorithms have been developed to solve various problems. In case of constraint processing we are searching for a feasible assignment of values to variables where the feasibility is defined by the constraints. This can be done in a backtracking manner where we assign a value to a selected variable and check whether

the constraints whose scope is already instantiated are satisfied. In the positive case, we proceed to the next variable. In the negative case, we try another value for the current variable or if there are no more values we backtrack to the last instantiated variable and try alternative values there. The following code shows the skeleton of this procedure called historically *labelling* (Waltz, 1975). Notice that the consistency check may prune domains of individual variables, which will be discussed in the next section.

```

procedure labelling(V,D,C)
  if all variables from V are assigned then return V
  select not-yet assigned variable x from V
  for each value v from Dx do
    (TestOK,D') ← consistent(V,D,C ∪ {x=v})
    if TestOK=true then
      R ← labelling(V,D',C)
      if R ≠ fail then return R
  end for
  return fail
end labelling
  
```

The above backtracking mechanism is parameterized by variable and value selection heuristics that decide about the order of variables for instantiation and about the order in which the values are tried. While value ordering is usually problem dependent and problem-independent heuristics are not frequently used due to their computational complexity, there are popular problem-independent variable ordering heuristics. Variable ordering is based on a so called *first-fail principle* formulated by Haralick and Eliot (1980) which says that the variable whose instantiation will lead to a failure with the highest probability should be tried first. A typical instance of this principle is a *dom* heuristic which prefers variables with the smallest domain for instantiation. There exist other popular variable ordering heuristics (Rossi *et al.*, 2006) such as *dom+deg* or *dom/deg*, but their detail description is out scope of this short article.

Though the heuristics influence (positively) efficiency of search they cannot resolve all drawbacks of backtracking. Probably the main drawback is ignoring the information about the reason of constraint infeasibility. If the algorithm discovers that no value can be assigned to a variable, it blindly backtracks to the last instantiated variable though the reason of the conflict may be elsewhere. There exist techniques like back-jumping that can detect the variable whose instantiation caused the problem and backtrack (backjump) to this

variable (Dechter, 2003). These techniques belong to a broader class of intelligent backtracking that shares the idea of intelligent recovery from the infeasibility. Though these techniques are interesting and far beyond simple enumeration, it seems better to prevent infeasibility rather than to recover from it (even in an intelligent way).

Domain Filtering and Maintaining Consistency

Assume variables A and B with domain $\{1, 2, 3\}$ and a simple constraint $A < B$. Clearly, value 3 can never be assigned to A because there is no way to satisfy the constraint $A < B$ if this value is used for A. Hence, this value can be safely removed from the domain of variable A and it does not need to be assumed during search. Similarly, value 1 can be removed from the domain of B. This process is called *domain filtering* and it is realised by a special procedure assigned to each constraint. Domain filtering is closely related to consistency of the constraint. We say that constraint C is (*arc*) *consistent* if for any value x in the domain of any variable in the scope of C there exist values in the domains of other variables in the scope of C such that the value tuple satisfies C. Such value tuple is called a *support* for x . Domain filtering attempts to make the constraint consistent by removing values which have no support.

Domain filtering can be applied to all constraints in the problem to remove unsupported values from the domains of variables and to make the whole problem consistent. Because the constraints are interconnected, it may be necessary to repeat the domain filtering of a constraint C if another constraint pruned the domain of variable in the scope of C. Basically the domain filtering is repeated until a fixed point is reached which removes the largest number of unsupported values. There exist several procedures to realise this idea (Mackworth, 1977), AC-3 schema is the most popular one:

```

procedure AC-3(V,D,C)
  Q ← C
  while non-empty Q do
    select c from Q
    D' ← c.FILTER(D)
    if any domain in D' is empty then return (fail,D')
    Q ← Q ∪ {c' ∈ C | ∃x ∈ var(c') D'x ≠ Dx} − {c}
    D ← D'
  end while
  return (true,D)

```

end AC-3

We did not cover the details of the filtering procedure here. In the simplest way, it may explore the consistent tuples in the constraint to find a support for each value. There exist more advanced techniques that keep some information between the repeated calls to the filter and hence achieve better time efficiency (Bessiere, 1994). Frequently, the filtering procedure exploits semantics of the constraint to realise filtering faster. For example, filtering for constraint $A < B$ can be realised by removing from the domain of A all values greater than the maximal value of B (and similarly for B).

Let us return our attention back to search. Even if we make all the constraints consistent, it does not mean that we obtained a solution. For example, the problem $(\{A, B, C\}, \{1, 2, 3\}, \{A \neq B, B \neq C\})$ is consistent in the above-described sense, but it has no solution. Hence consistency techniques need to be combined with backtracking search to obtain a complete constraint solver. First, we make the constraints consistent. Then we start the backtracking search as described in the previous section and after each variable instantiation, we make the constraints consistent again. It may happen that during the consistency procedure some domain becomes empty. This indicates inconsistency and we can backtrack immediately. Because the consistency procedure removes inconsistencies from the not yet instantiated variables, it prevents future conflicts during search. Hence this principle is called *look ahead* opposite to look back techniques that focus on recovery from discovered conflicts. The whole process is also called *maintaining consistency during search* and it can be realised by substituting the consistent procedure in labelling by the procedure AC-3. Figure 1 shows a difference between simple backtracking (top) and the look-ahead technique (bottom) when solving a well known 4-queens problem. The task is to allocate a queen to each column of the chessboard in such a way that no two queens attack each other. Notice that the look-ahead solved the method after four attempts while the simple backtracking is still allocating the first two queens.

Clearly, the more inconsistencies one can remove, the smaller search tree needs to be explored. There exist stronger consistency techniques that assume several constraints together (rather than filtering each constraint separately, as we described above), but they are usually too computationally expensive and hence they are not used in each node of the search tree. Nevertheless, there also exists a compromise between stronger and efficient

Figure 1. Solving 4-queens problem using backtracking (top) and look-ahead (bottom) techniques; the crosses indicate positions forbidden by the current allocation of queens in the look-ahead method (values pruned by AC).

domain filtering called a *global constraint*. The idea is to encapsulate some well defined sub-problem into a single constraint (rather than a set of constraints) and then design a fast filtering algorithm for this constraint. A typical example of such global constraint is all-different that encapsulates a set of binary inequalities between all pairs of variables and by using filtering based on matching in bipartite graphs, it achieves stronger pruning (Régin, 1994). Figure 2 demonstrates how a CSP with binary inequalities is converted into a bipartite graph, where matching indicates a consistent instantiation of variables.

Global constraints represent a powerful mechanism how to integrate efficient solving algorithms into general framework of constraint satisfaction. There exist dozens of global constraints designed for particular application areas (Baptiste *et al.*, 2001) as well as general global constraints (Beldiceanu *et al.*, 2005).

FUTURE TRENDS

Constraint processing is a mature technology that goes beyond artificial intelligence and co-operates (and competes) with techniques from areas such as operations research and discrete mathematics. Many constraint satisfaction techniques including dozens of specialized as well as generic global constraints have been developed in recent years (Beldiceanu *et al.*, 2005) and new techniques are coming. The technology trend is to integrate the techniques from different areas for co-operative and hybrid problem solving. Constraint processing may serve as a good base for such integration (as global constraints showed) but it can also provide solving techniques to be integrated in other frameworks such as SAT (satisfaction of logical formulas in a conjunctive normal form). This “hybridization and integration” trend is reflected in new conferences, for example

Figure 2. A graph representation of a constraint satisfaction problem with binary inequalities (left) and a bipartite graph representing the same problem in the all-different constraint (right).

CP-AI-OR (International Conference on Integration of AI and OR Techniques in Constraint Programming for Combinatorial Optimization Problems).

The paradox of fast technology development is that the technology is harder to use by non-expert users. There always exists several ways how to model a problem using constraints and though the models are equivalent concerning their soundness, they are frequently not equivalent concerning their efficiency. Although there are several rules of “good constraint modelling” (Marriott & Stuckey, 1998) (Barták, 2005) there do not exist generally applicable guidelines for constraint modelling. Hence it is sometimes not that easy to design a model that is solvable (in a reasonable time) by available constraint solvers. So one of the most important challenges of constraint processing for upcoming years is to bring the technology back to masses by providing automated modelling and problem reformulation tools that will form a middleware between the constraint solvers and non-expert users and make the holly grail of programming – the user states the problem and the computer solves it – a reality.

CONCLUSION

This article surveyed mainstream constraint satisfaction techniques with the goal to give a compact background of the technology to people who would like to use these techniques for solving combinatorial optimisation problems. We simplified the techniques and terminology a bit to fit the scope of the article while keeping the core principles. It is important to understand that the presented techniques (and even more) are already available in existing constraint solvers such as ILOGCP library (www.ilog.com/products/cp), SICStus Prolog (www.sics.se/sicstus), ECLiPSe (eclipse.crosscoreop.com), Mozart (www.mozart-oz.org), Choco (choco-solver.net) and other systems so the users are not required to program them from scratch. Nevertheless, understanding the underlying principles is important for design of efficient constraint models that can be solved by these systems. Constraint processing did not reach the holy grail of programming yet but it is going fast towards this goal.

KEY TERMS

Constrained Optimisation Problem (COP): A Constraint Satisfaction Problem extended by an objective function over the (subset of) decision variables. The task is to find a solution to the CSP which minimizes or maximizes the value of the objective function.

Constraint: Any relation between a subset of decision variables. Can be expressed extensionally, as a set of value tuples satisfying the constraint, or intentionally, using an arithmetical or logical formula between the variables, for example $A+B < C$.

Constraint Satisfaction Problem (CSP): A problem formulated using a set of decision variables, their domains, and constraints between the variables. The task is to find an instantiation of decision variables by values from their domains in such a way that all the constraints are satisfied.

Consistency Techniques: Techniques that remove inconsistent values (from variables' domains) or value tuples, that is, the values that cannot be assigned to a given variable in any solution. Arc consistency is the most widely used consistency technique.

Decision Variable: A variable modelling some feature of the problem, for example a start time of activity, whose value we are looking for in such a way that specified constraints are satisfied.

Domain of Variable: A set of possible values that can be assigned to a decision variable, for example a set of times when some activity can start. Constraint processing usually assumes finite domains only.

Domain Pruning (Filtering): A process of removing values from domains of variables that cannot take part in any solution. Usually, due to efficiency issues only the values locally violating some constraint are pruned. It is the most common type of consistency technique.

Global Constraint: An n-ary constraint modelling a subset of simpler constraints by providing a dedicated filtering algorithm that achieves stronger or faster domain pruning in comparison to making the simpler constraints (locally) consistent. All-different is an example of a global constraint.

Look Ahead: The most common technique for integrating depth-first search with maintaining consistency. Each time a search decision is done, it is propagated in the problem model by making the model consistent.

Search Algorithms: Algorithms that explore the space of possible (partial or complete) instantiations of decision variables with the goal to find an instantiation satisfying all the constraints (and optimizing the objective function in case of COP).

Continuous ACO in a SVR Traffic Forecasting Model

Wei-Chiang Hong

Oriental Institute of Technology, Taiwan

INTRODUCTION

The effective capacity of inter-urban motorway networks is an essential component of traffic control and information systems, particularly during periods of daily peak flow. However, slightly inaccurate capacity predictions can lead to congestion that has huge social costs in terms of travel time, fuel costs and environment pollution. Therefore, accurate forecasting of the traffic flow during peak periods could possibly avoid or at least reduce congestion. Additionally, accurate traffic forecasting can prevent the traffic congestion as well as reduce travel time, fuel costs and pollution.

However, the information of inter-urban traffic presents a challenging situation; thus, the traffic flow forecasting involves a rather complex nonlinear data pattern and unforeseen physical factors associated with road traffic situations. Artificial neural networks (ANNs) are attracting attention to forecast traffic flow due to their general nonlinear mapping capabilities of forecasting. Unlike most conventional neural network models, which are based on the empirical risk minimization principle, support vector regression (SVR) applies the structural risk minimization principle to minimize an upper bound of the generalization error, rather than minimizing the training errors. SVR has been used to deal with nonlinear regression and time series problems. This investigation presents a short-term traffic forecasting model which combines SVR model with continuous ant colony optimization (SVRCACO), to forecast inter-urban traffic flow. A numerical example of traffic flow values from northern Taiwan is employed to elucidate the forecasting performance of the proposed model. The simulation results indicate that the proposed model yields more accurate forecasting results than the seasonal autoregressive integrated moving average (SARIMA) time-series model.

BACKGROUND

Traditionally, there has been a wide variety of forecasting approaches applied to forecast the traffic flow of inter-urban motorway networks. Those approaches could be classified according to the type of data, forecast horizon, and potential end-use (Dougherty, 1996); including historical profiling (Okutani & Stephanedes, 1984), state space models (Stathopoulos & Karlaftis, 2003), Kalman filters (Whittaker, Garside & Lindveld, 1994), and system identification models (Vythoulkas, 1993). However, traffic flow data are in the form of spatial time series and are collected at specific locations at constant intervals of time. The above-mentioned studies and their empirical results have indicated that the problem of forecasting inter-urban motorway traffic flow is multi-dimensional, including relationships among measurements made at different times and geographical sites. In addition, these methods have difficulty coping with observation noise and missing values while modeling. Therefore, Danech-Pajouh and Aron (1991) employed a layered statistical approach with a mathematical clustering technique to group the traffic flow data and a separately tuned linear regression model for each cluster. Based on the multi-dimensional pattern recognition requests, such as intervals of time and geographical sites, non-parametric regression models (Smith, Williams & Oswald, 2002) have also successfully been employed to forecast motorway traffic flow. The ARIMA model and extended models are the most popular approaches in traffic flow forecasting (Kamarianakis & Prastacos, 2005) (Smith et al., 2002). Due to the stochastic nature and the strongly nonlinear characteristics of inter-urban traffic flow data, the artificial neural networks (ANNs) models have received much attention and been considered as alternatives for traffic flow forecasting models (Ledoux, 1997) (Yin, Wong, Xu & Wong, 2002). However, the training procedure of ANNs models is not only time consuming but also possible to get trapped in local minima and subjectively in selecting the model architecture.

Thus, SVR have been successfully employed to solve forecasting problems in many fields. Such as financial time series (stocks index and exchange rate) forecasting (Pai & Lin, 2005) (Pai, Lin, Hong & Chen, 2006), engineering and software field (production values and reliability) forecasting (Hong & Pai, 2006) (Pai & Hong, 2006), atmospheric science forecasting (Hong & Pai, 2007) (Mohandes, Halawani, Rehman & Hussain, 2004), and so on. Meanwhile, SVR model had also been successfully applied to forecast electric load (Pai & Hong, 2005a) (Pai & Hong, 2005b). The practical results indicated that poor forecasting accuracy is suffered from the lack of knowledge of the selection of the three parameters (σ , C , and ε) in a SVR model.

In this investigation, one of evolutionary algorithms, the ant colony optimization (ACO), is tried to determine the values of three parameters in a SVR traffic flow model in Panchiao city of Taipei County, Taiwan. In addition, as being developed for discrete optimization, the application of ACO to continuous optimization problems requires the transformation of a continuous search space to a discrete one by discretization of the continuous decision variables, which procedure is so-called CACO.

MAIN FOCUS OF THE CHAPTER

In this article, two models, the seasonal ARIMA (SARIMA) model and the SVRCACO model, are used to compare the forecasting performance of traffic flow.

Support Vector Regression (SVR) Model

The basic concept of the SVR is to map nonlinearly the original data x into a higher dimensional feature space. Hence, given a set of data $G = \{(x_i, a_i)\}_{i=1}^N$ (where x_i is the input vector; a_i is the actual value, and N is the total number of data patterns), the SVM regression function is:

$$f = g(x) = \mathbf{w}^T \phi(x_i) + b \quad (1)$$

where $\phi(x_i)$ is the feature of inputs (to map the input data into a so-called high dimensional feature space, see Fig. 1 (a) and (b)), and both w and b are coefficients. The coefficients (w and b) are estimated by minimizing the following regularized risk function

$$R(f) = C \frac{1}{N} \sum_{i=1}^N L_{\varepsilon}(a_i, f_i) + \frac{1}{2} \|\mathbf{w}\|^2 \quad (2)$$

where

$$L_{\varepsilon}(a, f) = \begin{cases} 0 & \text{if } |a - f| \leq \varepsilon \\ |a - f| - \varepsilon & \text{otherwise} \end{cases} \quad (3)$$

In addition, $L_{\varepsilon}(a, f)$ is employed to find out an optimum hyper plane on the high dimensional feature space to maximize the distance separating the training data into two subsets. Thus, the SVR focuses on finding the optimum hyper plane and minimizing the training error between the training data and the ε -insensitive loss function (as thick line in Fig. 1(c)).

Minimize:

$$R(w, \xi, \xi^*) = \frac{1}{2} \|\mathbf{w}\|^2 + C \left(\sum_{i=1}^N (\xi_i + \xi_i^*) \right) \quad (4)$$

with the constraints,

$$w\phi(x_i) + b - a_i \leq \varepsilon + \xi_i^*$$

$$a_i - w\phi(x_i) - b \leq \varepsilon + \xi_i$$

$$\xi_i, \xi_i^* \geq 0$$

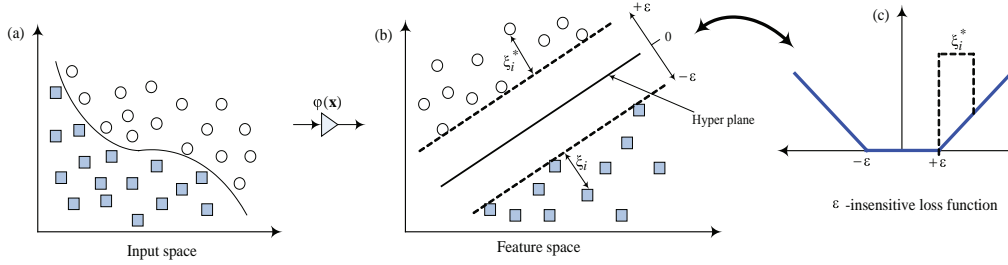

$$i = 1, 2, \dots, N$$

The first term of Eq. (5), employed the concept of maximizing the distance of two separated training data, is used to regularize weight sizes, to penalize large weights, and to maintain regression function flatness. The second term penalizes training errors of forecasting values and actual values by using the ε -insensitive loss function. C is a parameter to trade off these two terms. Training errors above ε are denoted as ξ_i^* , whereas training errors below ε are denoted as ξ_i .

After the quadratic optimization problem with inequality constraints is solved, the weight w in Eq. (2) is obtained,

$$w^* = \sum_{i=1}^N (\beta_i - \beta_i^*) K(x, x_i) \quad (5)$$

Figure 1. Transformation process illustration of a SVR model

Hence, the regression function is Eq. (6):

$$g(x, \beta, \beta^*) = \sum_{i=1}^N (\beta_i - \beta_i^*) K(x, x_i) + b \quad (6)$$

Here, $K(x_i, x_j)$ is called the Kernel function. The value of the Kernel equals the inner product of two vectors, x_i and x_j , in the feature space $\phi(x_i)$ and $\phi(x_j)$; that is, $K(x_i, x_j) = \phi(x_i) \cdot \phi(x_j)$. The Gaussian RBF kernel is not only easier to implement, but also capable to nonlinearly map the training data into an infinite dimensional space, thus, it is suitable to deal with nonlinear relationship problems. In this work, the Gaussian function, $\exp(-\|x - x_i\|^2 / 2\sigma^2)$, is used in the SVR model.

CACO in Selecting Parameters of the SVR Model

Ant colony optimization algorithms (Dorigo, 1992) have been successfully used to dealing with combinatorial optimization problems such as job-shop scheduling (Coloni, Dorigo, Maniezzo & Trubian, 1994), traveling salesman problem (Dorigo & Gambardella, 1997), space-planning (Bland, 1999), quadratic assignment problems (Maniezzo & Coloni, 1999), and data mining (Parpinelli, Lopes & Freitas, 2002). ACO imitates the behaviors of real ant colonies as they forage for food, wherein each ant lays down the pheromone on the path to the food sources or back to the nest. The paths with more pheromone are more likely to be selected by other ants. Over time, a colony of ants will select the shortest path to the food source and back to the nest. Therefore, a pheromone trail is the most important process for individual ant to smell and select its route.

The probability, $P_k(i, j)$, that an ant k moves from city i to city j is expressed as Eq. (7),

$$P_k(i, j) = \begin{cases} \arg \max_{S \in M_k} \{ [\tau(i, S)]^\alpha [\eta(i, S)]^\beta \} & , \text{ if } q \leq q_0 \\ \text{Eq.(9)} & , \text{ otherwise} \end{cases} \quad (7)$$

$$P_k(i, j) = \begin{cases} [\tau(i, j)]^\alpha [\eta(i, j)]^\beta / \sum_{S \in M_k} [\tau(i, S)]^\alpha [\eta(i, S)]^\beta & , \quad j \in M_k \\ 0 & , \text{ otherwise} \end{cases} \quad (8)$$

where $\tau(i, j)$ is the pheromone level between city i and city j , $\eta(i, j)$ is the inverse of the distance between cities i and j . In this study, the forecasting error represents the distance between cities. The α and β are parameters determining the relative importance of pheromone level and M_k is a set of cities in the next column of the city matrix for ant k . q is a random uniform variable $[0, 1]$ and the value q_0 is a parameter. The values of α , β and q_0 are set to be 8, 5 and 0.2 respectively.

Once ants have completed their tours, the most pheromone deposited by ants on the visited paths is considered as the information regarding the best paths from the nest to the food sources. Therefore, the pheromone dynamic updating plays the main role in real ant colonies searching behaviors. The local and global updating rules of pheromone are expressed as Eq.(9) and Eq(10) respectively.

$$\tau(i, j) = (1 - \rho)\tau(i, j) + \rho \tau_0 \quad (9)$$

$$\tau(i, j) = (1 - \delta)\tau(i, j) + \delta \Delta\tau(i, j) \quad (10)$$

where ρ is the local evaporation rate of pheromone, $0 < \rho < 1$; τ_0 is the initial amount of pheromone deposited on each of the paths. In this work, the values of ρ and τ_0 are set to be 0.01 and 1 correspondingly. In addition, the approach proposed by Dorigo and Gambardella (1994) was employed here for generating the initial amount of pheromone. Global trail updating is accomplished according Eq.(10). The δ is the global pheromone decay parameter, $0 < \delta < 1$, and set to be 0.2 for this study. The $\Delta\tau(i, j)$, expressed as Eq.(11), is used to increase the pheromone on the path of the solution.

$$\Delta\tau(i, j) = \begin{cases} 1/L & , \text{ if } (i, j) \in \text{global best route} \\ 0 & , \text{ otherwise} \end{cases} \quad (11)$$

where L is the length of the shortest route.

A Numerical Example and Experimental Results

The traffic flow data sets were originated from three Civil Motorway detector sites. The Civil Motorway is the busiest inter-urban motorway networks in Panchiao city, the capital of Taipei County, Taiwan. The major site was located at the center of Panchiao City, where the flow intersects an urban local street system, and it provided one way traffic volume for each hour in weekdays. Therefore, one way flow data for peak traffic are employed in this investigation, which includes the morning peak period (MPP; from 6:00 to 10:00) and the evening peak period (EPP; from 16:00 to 20:00). The data collection is conducted from February 2005 to March 2005, the number of traffic flow data available for MPP and EPP are 45 and 90 hours, respectively. For convenience, the traffic flow data are converted to equivalent of passengers (EOP), and both of these two peak periods show the seasonality of traffic data. In addition, traffic flow data are divided into three parts: training data (MPP 25 hours; EPP 60 hours), validation data (MPP 10 hours; EPP 15 hours) and testing data (MPP 10 hours; EPP 15 hours). The accuracy of forecasting models is measured by the normalized root mean square error (NRMSE), as given by Eq.(12).

$$NRMSE = \sqrt{\frac{\sum_{i=1}^n (a_i - f_i)^2}{\sum_{i=1}^n a_i^2}} \quad (12)$$

where n is the number of forecasting periods; a_i is the actual traffic flow value at period i ; and f_i is the forecasting traffic flow value at period i .

The parameter selection of forecasting models is important for obtaining good forecasting performance. For the SARIMA model, the parameters are determined by taking the first-order regular difference and first seasonal difference to remove non-stationary and seasonality characteristics. Using statistical packages, with no residuals autocorrelated and approximately white noise residuals, the most suitable models for these two morning/evening peak periods for the traffic data are SARIMA(1,0,1) \times (0,1,1)₅ with non-constant item and SARIMA(1,0,1) \times (1,1,1)₅ with constant item, respectively. The equations used for the SARIMA models are presented as Eqs. (13) and (14), respectively.

$$(1 - 0.5167B)(1 - B^5)X_t = (1 + 0.3306B)(1 - 0.9359B^5)\epsilon_t \quad (13)$$

$$(1 - 0.5918B)(1 - B^5)X_t = 2.305 + (1 - 0.9003B^5)\epsilon_t \quad (14)$$

For the SVRCACO model, a rolling-based forecasting procedure was conducted and a one-hour-ahead forecasting policy adopted. Then, several types of data-rolling are considered to forecast traffic flow in the next hour. In this investigation, the CACO is employed to determine suitable combination of the three parameters in a SVR model. Parameters of the SVRCACO models with the minimum testing NRMSE values were selected as the most suitable model for this investigation. **Table 1** indicates that SVRCACO models perform the best when 15 and 35 input data are used for morning/evening traffic forecast respectively. **Table 2** compares the forecasting accuracy of the SARIMA and SVRCACO models in terms of NRMSE. It is illustrated that SVRCACO models have better forecasting results than the SARIMA models.

FUTURE TRENDS

In this investigation, the SVRCACO model provides a convenient and valid alternative for traffic flow forecasting. The SVRCACO model directly uses historical observations from traffic control systems and then determines suitable parameters by efficient optimiza-

tion algorithms. In future research, other factors and meteorological control variables during peak periods, such as driving speed limitation, important social events, the percentage of heavy vehicles, bottleneck service level and waiting time during intersection traffic signals can be included in the traffic forecasting model. In addition, some other advanced optimization algorithms for parameters selection can be applied for the SVR model to satisfy the requirement of real-time traffic control systems.

CONCLUSION

Accurate traffic forecast is crucial for the inter-urban traffic control system, particularly for avoiding congestion and for increasing efficiency of limited traffic resources during peak periods. The historical traffic data of Panchiao City in northern Taiwan shows a seasonal fluctuation trend which occurs in many inter-urban traffic systems. Therefore, over-prediction or under-prediction of traffic flow influences the transportation capability of an inter-urban system. This study introduces the application of forecasting techniques, SVRCACO, to investigate its feasibility for forecasting inter-urban motorway traffic. This article indicates that the SVR-CACO model has better forecasting performance than the SARIMA model. The superior performance of the SVRCACO model is due to the generalization ability of SVR model for forecasting and the proper selection of SVR parameters by CACO.

KEY TERMS

Ant Colony Optimization Algorithm (ACO): inspired by the behavior of ants in finding paths from the colony to food, is a probabilistic technique for solving computational problems which can be reduced to

finding good paths through graphs. A short path gets marched over faster, and thus the pheromone density remains high as it is laid on the path as fast as it can evaporate.

Artificial Neural Networks (ANNs): A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data.

Autoregressive Integrated Moving Average (ARIMA): A generalization of an autoregressive moving average (ARMA) model. These models are fitted to time series data either to better understand the data or to predict future points in the series. The model is generally referred to as an ARIMA(p, d, q) model where p, d , and q are integers greater than or equal to zero and refer to the order of the autoregressive, integrated, and moving average parts of the model respectively.

Evolutionary Algorithm (EA): is a generic population-based meta-heuristic optimization algorithm. An EA uses some mechanisms inspired by biological evolution: reproduction, mutation, recombination, natural selection and survival of the fittest. Evolutionary algorithms consistently perform well approximating solutions to all types of problems because they do not make any assumption about the underlying fitness landscape.

Pheromone: A pheromone is a chemical that triggers an innate behavioral response in another member of the same species. There are alarm pheromones, food trail pheromones, sex pheromones, and many others that affect behavior or physiology. In this article, food trail pheromones are employed, which are common in social insects.

Seasonal Autoregressive Integrated Moving Average (SARIMA): A kind of ARIMA model to conduct forecasting problem while seasonal effect is suspected. For example, consider a model of daily road traffic volumes. Weekends clearly exhibit different behavior from weekdays. In this case it is often considered better to use a SARIMA (seasonal ARIMA) model than to increase the order of the AR or MA parts of the model.

Support Vector Machines (SVMs): Support vector machines (SVMs) were originally developed to solve pattern recognition and classification problems. With

the introduction of Vapnik's ϵ -insensitive loss function, SVMs have been extended to solve nonlinear regression estimation problems which are so-called support vector regression (SVR). SVR applies the structural risk minimization principle to minimize an upper bound of the generalization error. SVR has been used to deal with nonlinear regression and time series problems.

Data Mining Fundamental Concepts and Critical Issues

INTRODUCTION

Data mining is the process of extracting previously unknown information from large databases or data warehouses and using it to make crucial business decisions. Data mining tools find patterns in the data and infer rules from them. The extracted information can be used to form a prediction or classification model, identify relations between database records, or provide a summary of the databases being mined. Those patterns and rules can be used to guide decision making and forecast the effect of those decisions, and data mining can speed analysis by focusing attention on the most important variables.

BACKGROUND

We are drowning in data, but starving for knowledge. In recent years the amount or the volume of information has increased significantly. Some researchers suggest that the volume of information stored doubles every year. Disk storage per person (DSP) is a way to measure the growth in personal data. Edelstein (2003) estimated that the number has dramatically grown from 28MB in 1996 to 472MB in 2000.

Data mining seems to be the most promising solution for the dilemma of dealing with too much data having very little knowledge. By using pattern recognition technologies and statistical and mathematical techniques to sift through warehoused information, data mining helps analysts recognize significant facts, relationships, trend, patterns, exceptions and anomalies. The use of data mining can advance a company's position by creating a sustainable competitive advantage. Data

warehousing and mining is the science of managing and analyzing large datasets and discovering novel patterns (Davenport & Harris, 2007; Wang, 2006; Olafsson, 2006).

Data mining is taking off for several reasons: organizations are gathering more data about their businesses, the enormous drop in storage costs, competitive business pressures, a desire to leverage existing information technology investments, and the dramatic drop in the cost/performance ratio of computer systems. Another reason is the rise of data warehousing. In the past, it was often necessary to gather the data, cleanse it, and merge it. Now, in many cases, the data are already sitting in a data warehouse ready to be used.

Over the last 40 years, the tools and techniques to process data and information have continued to evolve from data bases to data warehousing and further to data mining. Data warehousing applications have become business-critical. Data mining can compress even more value out of these huge repositories of information. Data mining is a multidisciplinary field covering a lot of disciplines such as databases, statistics, artificial intelligence, pattern recognition, machine learning, information theory, control theory, operations research, information retrieval, data visualization, high-performance computing or parallel and distributed computing, etc (Zhou, 2003; (Hand, Mannila, & Smyth, 2001).

Certainly, many statistical models had emerged a long time ago. Machine learning has marked a milestone in the evolution of computer science. Although data mining is still in its infancy, it is now being used in a wide range of industries and for a range of tasks in a variety of contexts (Wang, 2003; Lavoie, Dempsey, & Connaway, 2006). Data mining is synonymous with knowledge discovery in databases, knowledge extrac-

tion, data/pattern analysis, data archeology, data dredging, data snooping, data fishing, information harvesting, and business intelligence (Han and Kamber, 2001).

MAIN FOCUS

Functionalities and Tasks

The common types of information that can be derived from data mining operations are associations, sequences, classifications, clusters, and forecasting. Associations happen when occurrences are linked in a single event. One of the most popular association applications deals with market basket analysis. This technique incorporates the use of frequency and probability functions to estimate the percentage chance of occurrences. Business strategists can leverage off of market basket analysis by applying such techniques as cross-selling and up-selling. In sequences, events are linked over time. This is particularly applicable in e-business for Website analysis.

Classification is probably the most common data mining activity today. It recognizes patterns that describe the group to which an item belongs. It does this by examining existing items that already have been classified and inferring a set of rules from them. Clustering is related to classification, but differs in that no groups have yet been defined. Using clustering, the data-mining tool discovers different groupings within the data. The resulting groups or clusters help the end user make some sense out of vast amounts of data (Kudyba, & Hoptroff, 2001). All of these applications may involve predictions. The fifth application type, forecasting, is a different form of prediction. It estimates the future value of continuous variables based on patterns within the data.

Algorithms and Methodologies

Neural Networks

Also referred to as artificial intelligence (AI), neural networks utilize predictive algorithms. This technology has many similar characteristics to that of regression because the application generally examines historical data, and utilizes a functional form that best equates explanatory variables and the target variable in a man-

ner that minimizes the error between what the model had produced and what actually occurred in the past, and then applies this function to future data. Neural networks are a bit more complex as they incorporate intensive program architectures in attempting to identify linear, non-linear and patterned relationships in historical data.

Decision Trees

Megaputer (2006) mentioned that this method can be applied for solution of classification tasks only. As a result of applying this method to a training set, a hierarchical structure of classifying rules of the type “if...then...” is created. This structure has a form of a tree. In order to decide to which class an object or a situation should be assigned one has to answer questions located at the tree nodes, starting from the root. Following this procedure one eventually comes to one of the final nodes (called leaves), where the analyst finds a conclusion to which class the considered object should be assigned.

Genetic Algorithms (or Evolutionary Programming)

Genetic algorithms, biologically inspired search method, borrow mechanisms of inheritance to find solutions. Biological systems demonstrated flexibility, robustness and efficiency. Many biological systems are good at adapting to their environments. Some biological methods (such as reproduction, crossover and mutation) can be used as an approach to computer-based problem solving. An initial population of solutions is created randomly. Only a fixed number of candidate solutions are kept from one generation to the next. Those solutions that are less fit tend to die off, similar to the biological notion of “survival of the fittest”.

Regression Analysis

This technique involves specifying a functional form that best describes the relationship between explanatory, driving or independent variables and the target or dependent variable the decision maker is looking to explain. Business analysts typically utilize regression to identify the quantitative relationships that exist between variables and enable them to forecast into the future.

Regression models also enable analysts to perform “what if” or sensitivity analysis. Some examples include how response rates change if a particular marketing or promotional campaign is launched, or how certain compensation policies affect employee performance and many more.

Logistics Regression

Logistic regression should be used when you want to predict the outcome of a dichotomous (e.g., yes/no) variable. This method is used for data that is not normally distributed (bell-shaped curve) i.e., categorical (coded) data. When a dependent variable can only have one of two answers, such as “will graduate” or “will not graduate”, you cannot get a normal distribution as previously discussed.

Memory Based Reasoning (MBR) or the Nearest Neighbor Method

To forecast a future situation, or to make a correct decision, such systems find the closest past analogs of the present situation and choose the same solution which was the right one in those past situations. The drawback of this application is that there is no guarantee that resulting clusters provide any value to the end user. Resulting clusters may just not make any sense with regards to the overall business environment. Because of limitations of this technique, no predictive, “what if” or variable/target connection can be implemented.

The key differentiator between classification and segmentation with that of regression and neural network technology mentioned above is the inability of the former to perform sensitivity analysis or forecasting.

Applications and Benefits

Data mining can be used widely in science and business areas for analyzing databases, gathering data and solving problems. In line with Berry and Linoff (2004), the benefits data mining can provide for businesses are limitless. Here are just a few examples:

- *Identify best prospects and then retain them as customers.*
By concentrating marketing efforts only on the best prospects, companies will save time and money,

thus increasing effectiveness of their marketing operation.

- *Predict cross-sell opportunities and make recommendations.*

Both traditional and Web-based operations can help customers quickly locate products of interest to them and simultaneously increase the value of each communication with the customers.

- *Learn parameters influencing trends in sales and margins.*

In the majority of cases we have no clue on what combination of parameters influences operation (black box). In these situations data mining is the only real option.

- *Segment markets and personalize communications.*

There might be distinct groups of customers, patients, or natural phenomena that require different approaches in their handling.

The importance of collecting data that reflect specific business or scientific activities to achieve competitive advantage is widely recognized. Powerful systems for collecting data and managing it in large databases are in place in all large and mid-range companies. However, the bottleneck of turning this data into information is the difficulty of extracting knowledge about the system being studied from the collected data. Human analysts without special tools can no longer make sense of enormous volumes of data that require processing in order to make informed business decisions (Kudyba & Hoptroff, 2001).

The applications of data mining are everywhere: from biomedical data (Hu and Xu, 2005) to mobile user data (Goh and Taniar, 2005); from data warehousing (Tjioe and Taniar, 2005) to intelligent web personalization (Zhou, Cheung, & Fong, 2005); from analyzing clinical outcome (Hu, Song, Han, Yoo, Prestrud, Brennan, & Brooks, 2005) to mining crime patterns (Bagui, 2006).

Potential Pitfalls

Data Quality

Data quality means the accuracy and completeness of the data. Data quality is a versatile issue that represents one of the biggest challenges for data mining.

Data quality problem is of great importance due to the emergence of large volumes of data. Many business and industrial applications critically rely on the quality of information stored in diverse databases and data warehouses. As Seifert (2004) emphasized that data quality can be affected by the structure and consistency of the data being analyzed. Other factors like the presence of duplicate records, the lack of data standards, the timeliness of updates and human errors can significantly impact the effectiveness of complex data mining techniques, which are sensitive to subtle differences in data. To improve the quality of data it is sometimes necessary to clean data by removing the duplicate records, standardizing the values or symbols used in the database to represent certain information, accounting for missing data points, removing unneeded data fields, identifying abnormal data points.

Interoperability

Interoperability refers to the ability of computer system and/or data to work with other systems or data using common standards or process. Until recently, some government agencies elected not to gamble with any level of open access and operated isolated information systems. But isolated data is in many ways useless data; bits of valuable information on the Sept. 11, 2001 hijackers' activities may have been stored in a variety of databases at the federal, state, and local government levels, but that information was not collected and available to those who needed to see it to glimpse a complete picture of the growing threat. So Seifert (2004) suggested that it is a critical part of the larger efforts to improve interagency collaboration and information sharing. For public data mining, interoperability of databases and software is important to enable the search and analysis of multiple databases simultaneously. This also ensures the compatibility of data mining activities of different agencies.

Standardization

This allows you to arrange customer information in a consistent format. Among the biggest challenges are inconsistent abbreviations, and misspellings and variant spellings. Among the types of data that can be

appended are demographic, geographic, psychographic, behavioristic, event-driven and computed. Matching allows you to identify similar data within and across your data sources. One of the greatest challenges of matching is creating a system that incorporates your "business rules," or criteria for determining what constitutes a match.

Preventing Decay

The worst enemy of information is time. And information decays at different rates (Berry & Linoff, 2004). Cleaning your database is a large accomplishment, but it will be short-lived if you fail to implement procedures for keeping it clean at the source. According to the second law of thermodynamics, ordered systems tend to disorder, and a database is a very ordered system. Contacts move. Companies grow. Knowledge workers enter new customer information incorrectly.

Some information simply starts out wrong, result of data input errors such as typos, transpositions, omissions and other mistakes. These are often easy to avoid. Finding ways to successfully implement these new technologies into a comprehensive data quality program not only increases the quality of your customer information, but also saves time, reduces frustration, improves customer relations, and ultimately increases revenue. Without constant attention to quality, your information quality will disintegrate.

No Generalizations to a Population

In statistics a population is defined, and then a sample is collected to make inferences about the population. This means that data cannot be re-used. They define a model before looking at the data. Data mining does not attempt generalizations to a population. The database is considered as the population. With the computing power of modern computers data miners can use the whole database, making sampling redundant. Data can be re-used. In data mining it is a common practice to try hundreds of models and find the one that fits best. This makes the interpretation of the significance difficult. Machine learning is the data mining equivalent to regression. In machine learning we use a training set to train the system to find the dependent variable.

FUTURE TRENDS

Predictive Analysis

Augusta (2004) suggested that predictive analysis is one of the major future trends for data mining. Rather than being just about mining large amounts of data, predictive analytics looks to actually understand the data content. They hope to forecast based on the contents of the data. However this requires complex programming and a great amount of business acumen. They are looking to do more than simply archive data, which is what data mining is currently known for. They want to not just process it, but understand it more clearly which will in turn allow them to make better predictions about future behavior. With predictive analytics you have the program scour the data and try to form, or help form, new hypotheses itself. This shows great promise, and would be a boon for industries everywhere.

Diversity of Application Domains

Data mining and X” phenomenon, as Tuzhilin (2006) coined, where X constitutes a broad range of fields in which data mining is used for analyzing the data. This has resulted in a process of cross-fertilization of ideas generated within this diverse population of researchers interacting across the traditional boundaries of their disciplines. The next generation of data mining applications covers a large number of different fields from traditional businesses to advance scientific research. Kantardzic & Zurada (2005) observed that with new tools, methodologies, and infrastructure, this trend of diversification will continue each year.

CONCLUSION

The emergence of new information technologies has given us much more data and many more options how to use it. Yet managing that flood of data, and making it useful and available to decision makers has been a major organizational challenge. Data mining allows the extraction of diamonds of knowledge from huge historical mines of data. It helps to predict outcomes of future situations, to optimize business decisions, to increase the value of each customer and communication, and to improve customer satisfaction.

The management of data requires understanding and a skill set far beyond mere programming. Managing data mining is a new revelation as analysts will have to sift through more and more information daily due to the ever increasing size of the Web and consumer purchases. Data mining can have enormous rewards if properly used. We have an unprecedented opportunity for the future is we could avoid data mining’s pitfalls.

KEY TERMS

Data Mining: The process of automatically searching large volumes of data for patterns. Data mining is a fairly recent and contemporary topic in computing.

Data Visualization: A technology for helping users to see patterns and relationships in large amounts of data by presenting the data in graphical form.

Explanatory Variables: Used interchangeably and refer to those variables that explain the variation of a particular target variable. Also called driving, or descriptive, or independent variables.

Information Quality Decay: Quality of some data goes down when facts about real world objects change over time, but those facts are not updated in the database.

Information Retrieval: The art and science of searching for information in documents, searching for documents themselves, searching for metadata which describe documents, or searching within databases, whether relational stand-alone databases or hypertext networked databases such as the Internet or intranets, for text, sound, images or data.

Machine Learning: Concerned with the development of algorithms and techniques, which allow computers to "learn".

Neural Networks: Also referred to as artificial intelligence (AI), which utilizes predictive algorithms.

Pattern Recognition: The act of taking in raw data and taking an action based on the category of the data. It is a field within the area of machine learning.

Predictive Analysis: Use of data mining techniques, historical data, and assumptions about future conditions to predict outcomes of events.

Segmentation: Another major group that comprises the world of data mining involving technology that identifies not only statistically significant relationships between explanatory and target variables, but determines noteworthy segments within variable categories that illustrate prevalent impacts on the target variable.

Data Warehousing Development and Design Methodologies

INTRODUCTION

Information systems were developed in early 1960s to process orders, billings, inventory controls, payrolls, and accounts payables. Soon information systems research began. Harry Stern started the “Information Systems in Management Science” column in *Management Science* journal to provide a forum for discussion beyond just research papers (Banker & Kauffman, 2004). Ackoff (1967) led the earliest research on management information systems for decision-making purposes and published it in *Management Science*. Gorry and Scott Morton (1971) first used the term ‘decision support systems’ (DSS) in a paper and constructed a framework for improving management information systems. The topics on information systems and DSS research diversifies. One of the major topics has been on how to get systems design right.

As an active component of DSS, which is part of today’s business intelligence systems, data warehousing became one of the most important developments in the information systems field during the mid-to-late 1990s. Since business environment has become more global, competitive, complex, and volatile, customer relationship management (CRM) and e-commerce initiatives are creating requirements for large, integrated data repositories and advanced analytical capabilities. By using a data warehouse, companies can make decisions about customer-specific strategies such as customer profiling, customer segmentation, and cross-selling analysis (Cunningham et al., 2006). Thus how to design and develop a data warehouse have become important issues for information systems designers and developers.

This paper presents some of the currently discussed development and design methodologies in data warehousing, such as the multidimensional model vs. relational ER model, CIF vs. multidimensional meth-

odologies, data-driven vs. metric-driven approaches, top-down vs. bottom-up design approaches, data partitioning and parallel processing.

BACKGROUND

Data warehouse design is a lengthy, time-consuming, and costly process. Any wrongly calculated step can lead to a failure. Therefore, researchers have placed important efforts to the study of design and development related issues and methodologies.

Data modeling for a data warehouse is different from operational database data modeling. An operational system, e.g., online transaction processing (OLTP), is a system that is used to run a business in real time, based on current data. An OLTP system usually adopts Entity-relationship (ER) modeling and application-oriented database design (Han & Kamber, 2006). An information system, like a data warehouse, is designed to support decision making based on historical point-in-time and prediction data for complex queries or data mining applications (Hoffer, et al., 2007). A data warehouse schema is viewed as a dimensional model (Ahmad et al., 2004, Han & Kamber, 2006; Levene & Loizou, 2003). It typically adopts either a star or snowflake schema and a subject-oriented database design (Han & Kamber, 2006). The schema design is the most critical to the design of a data warehouse.

Many approaches and methodologies have been proposed in the design and development of data warehouses. Two major data warehouse design methodologies have been paid more attention. Inmon et al. (2000) proposed the Corporate Information Factory (CIF) architecture. This architecture, in the design of the atomic-level data marts, uses denormalized entity-relationship diagram (ERD) schema. Kimball (1996, 1997) proposed multidimensional (MD) architecture.

This architecture uses star schema at atomic-level data marts. Which architecture should an enterprise follow? Is one better than the other?

Currently, the most popular data model for data warehouse design is the dimensional model (Han & Kamber, 2006; Bellatreche, 2006). Some researchers call this model the data-driven design model. Artz (2006), nevertheless, advocates the metric-driven model, which, as another view of data warehouse design, begins by identifying key business processes that need to be measured and tracked over time in order for the organization to function more efficiently. There has always been the issue of top-down vs. bottom-up approaches in the design of information systems. The same is with a data warehouse design. These have been puzzling questions for business intelligent architects and data warehouse designers and developers. The next section will extend the discussion on issues related to data warehouse design and development methodologies.

DESIGN AND DEVELOPMENT METHODOLOGIES

Data Warehouse Data Modeling

Database design is typically divided into a four-stage process (Raisinghani, 2000). After requirements are collected, conceptual design, logical design, and physical design follow. Of the four stages, logical design is the key focal point of the database design process and most critical to the design of a database. In terms of an OLTP system design, it usually adopts an ER data model and an application-oriented database design (Han & Kamber, 2006). The majority of modern enterprise information systems are built using the ER model (Raisinghani, 2000). The ER data model is commonly used in relational database design, where a database schema consists of a set of entities and the relationship between them. The ER model is used to demonstrate detailed relationships between the data elements. It focuses on removing redundancy of data elements in the database. The schema is a database design containing the logic and showing relationships between the data organized in different relations (Ahmad et al., 2004). Conversely, a data warehouse requires a concise, subject-oriented schema that facilitates online data analysis. A data warehouse schema is viewed as a dimensional model which is composed of a central fact

table and a set of surrounding dimension tables, each corresponding to one of the components or dimensions of the fact table (Levene & Loizou, 2003). Dimensional models are oriented toward a specific business process or subject. This approach keeps the data elements associated with the business process only one join away. The most popular data model for a data warehouse is multidimensional model. Such a model can exist in the form of a star schema, a snowflake schema, or a starflake schema.

The star schema (see Figure 1) is the simplest database structure containing a fact table in the center, no redundancy, which is surrounded by a set of smaller dimension tables (Ahmad et al., 2004; Han & Kamber, 2006). The fact table is connected with the dimension tables using many-to-one relationships to ensure their hierarchy. The star schema can provide fast response time allowing database optimizers to work with simple database structures in order to yield better execution plans.

The snowflake schema (see Figure 2) is a variation of the star schema model, in which all dimensional information is stored in the third normal form, thereby further splitting the data into additional tables, while keeping fact table structure the same. To take care of hierarchy, the dimension tables are connected with sub-dimension tables using many-to-one relationships. The resulting schema graph forms a shape similar to a snowflake (Ahmad et al., 2004; Han & Kamber, 2006). The snowflake schema can reduce redundancy and save storage space. However, it can also reduce the effectiveness of browsing and the system performance may be adversely impacted. Hence, the snowflake schema is not as popular as star schema in data warehouse design (Han & Kamber, 2006). In general, the star schema requires greater storage, but it is faster to process than the snowflake schema (Kroenke, 2004).

The starflake schema (Ahmad et al., 2004), also called galaxy schema or fact constellation schema (Han & Kamber, 2006), is a combination of the denormalized star schema and the normalized snowflake schema (see Figure 3). The starflake schema is used in situations where it is difficult to restructure all entities into a set of distinct dimensions. It allows a degree of crossover between dimensions to answer distinct queries (Ahmad et al., 2004). Figure 3 illustrates the starflake schema.

What needs to be differentiated is that the three schemas are normally adopted according to the differ-

Figure 1. Example of a star schema (adapted from Kroenke, 2004)

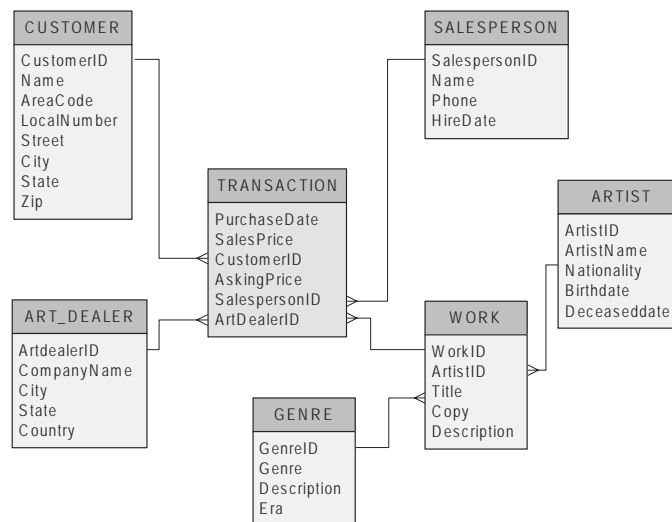

Figure 2. Example of a snowflake schema (adapted from Kroenke, 2004)

ences of design requirements. A data warehouse collects information about subjects that span the entire organization, such as customers, items, sales, etc. Its scope is enterprise-wide (Han & Kamber, 2006). Starflake schema can model multiple and interrelated subjects. Therefore, it is usually used to model an enterprise-wide data warehouse. A data mart, on the other hand, is similar to a data warehouse but limits its focus to

a department subject of the data warehouse. Its scope is department-wide. The star schema and snowflake schema are geared towards modeling single subjects. Consequently, the star schema or snowflake schema is commonly used for a data mart modeling, although the star schema is more popular and efficient (Han & Kamber, 2006).

Figure 3. Example of a starflake schema (galaxy schema or fact constellation) (adapted from Han & Kamber, 2006)

CIF vs. Multidimensional

Two major design methodologies have been paid more attention in the design and development of data warehouses. Kimball (1996, 1997) proposed multidimensional (MD) architecture. Inmon, Gallemmco, and Geiger (2000) proposed the Corporate Information Factory (CIF) architecture. Imhoff et al. (2004) made a comparison between the two by using important criteria, such as scope, perspective, data flow, etc. One of the most significant differences between the CIF and MD architectures is the definition of data mart. For MD architecture, the design of the atomic-level data marts is significantly different from the design of the CIF data warehouse, while its aggregated data mart schema is approximately the same as the data mart in the CIF architecture. MD architecture uses star schemas, whereas CIF architecture uses denormalized ERD schema. This data modeling difference constitutes the main design difference in the two architectures (Imhoff et al., 2004). A data warehouse may need both types of data marts in the data warehouse bus architecture depending on the business requirements. Unlike the CIF architecture, there is no physical repository equivalent to the data warehouse in the MD architecture.

The design of the two data marts is predominately multidimensional for both architecture, but the CIF architecture is not limited to just this design and can support a much broader set of data mart design techniques. In terms of scope, both architectures deal with enterprise scope and business unit scope, with CIF architecture putting a higher priority on enterprise scope and MD

architecture placing a higher priority on business unit scope. Imhoff et al. (2004) encourage the application of a combination of the data modeling techniques in the two architectural approaches, namely, the ERD or normalization techniques for the data warehouse and the star schema data model for multidimensional data marts. A CIF architecture with only a data warehouse and no multidimensional marts is almost useless and a multidimensional data-mart-only environment risks the lack of an enterprise integration and support for other forms of business intelligence analyses.

Data-Driven vs. Metric-Driven

Currently, the most popular data model for data warehouse design is the dimensional model (Han & Kamber, 2006; Bellatreche, 2006). In this model, data from OLTP systems are collected to populated dimensional model. Researchers term a data warehouse design based on this model as a data-driven design model since the information acquisition processes in the data warehouse are driven by the data made available in the underlying operational information systems. Another view of data warehouse design is called the metric-driven view (Artz, 2006), which begins by identifying key business processes that need to be measured and tracked over time in order for the organization to function more efficiently. Advantages of data-driven model include that it is more concrete, evolutionary, and uses derived summary data. Yet the information generated from the data warehouse may be meaningless to the user owing to the fact that the nature of the

derived summary data from OLTP systems may not be clear. The metric-driven design approach, on the other hand, begins first by defining key business processes that need to be measured and tracked over time. After these key business processes are identified, then they are modeled in a dimensional data model. Further analysis follows to determine how the dimensional model will be populated (Artz, 2006).

According to Artz (2006), data-driven model to a data warehouse design has little future since information derived from a data-driven model is information about the data set. Metric-driven model, conversely, is possibly to have some key impacts and implications because information derived from a metric-driven model is information about the organization. Data-driven approach is dominating data warehouse design in organizations at present. Metric-driven, on the other hand, is at its research stage, needing practical application testimony of its speculated potentially dramatic implications.

Top-Down vs. Bottom-Up

There are two approaches in general to building a data warehouse prior to the data warehouse construction commencement, including data marts: the top-down approach and bottom-up approach (Han & Kamber, 2006; Imhoff et al., 2004; Marakas, 2003). Top-down approach starts with a big picture of the overall, enterprise-wide design. The data warehouse to be built is large and integrated, with a focus on integrating the enterprise data for usage in any data mart from the very first project (Imhoff et al., 2004). It implies a strategic rather than an operational perspective of the data. It serves as the proper alignment of an organization's information systems with its business goals and objectives (Marakas, 2003). However, this approach is risky (Ponniiah, 2001). In contrast, a bottom-up approach is to design the warehouse with business-unit needs for operational systems. It starts with experiments and prototypes (Han & Kamber, 2006). With bottom-up, departmental data marts are built first one by one. It offers faster and easier implementation, favorable return on investment, and less risk of failure, but with a drawback of data fragmentation and redundancy. The focus of bottom-up approach is to meet unit-specific needs with minimum regards to the overall enterprise-wide data requirements (Imhoff et al., 2004).

An alternative to the above-discussed two approaches is to use a combined approach (Han & Kamber, 2006), with which "an organization can exploit the planned and strategic nature of the top-down approach while retaining the rapid implementation and opportunistic application of the bottom-up approach" (p. 129), when such an approach is necessitated in the undergoing organizational and business scenarios.

Data Partitioning and Parallel Processing

Data partitioning is the process of decomposing large tables (fact tables, materialized views, indexes) into multiple small tables by applying the selection operators (Bellatreche, 2006). A good partitioning scheme is an essential part of designing a database that will benefit from parallelism (Singh, 1998). With a well performed partitioning, significant improvements in availability, administration, and table scan performance can be achieved.

Parallel processing is based on a parallel database, in which multiprocessors are in place. Parallel databases link multiple smaller machines to achieve the same throughput as a single, larger machine, often with greater scalability and reliability than single processor databases (Singh, 1998). In a context of relational online analytical processing (ROLAP), by partitioning data of ROLAP schema (star schema or snowflake schema) among a set of processors, OLAP queries can be executed in a parallel, potentially achieving a linear speedup and thus significantly improving query response time (Datta et al., 1998; Tan, 2006). Given the size of contemporary data warehousing repositories, multiprocessor solutions are crucial for the massive computational demands for current and future OLAP system (Dehne et al., 2006). The assumption of most of the fast computation algorithms is that their algorithms can be applied into the parallel processing system (Dehne, 2006; Tan, 2006). As a result, it is sometimes necessary to use parallel processing for data mining because large amounts of data and massive search efforts are involved in data mining (Turban et al., 2005). Therefore, data partitioning and parallel processing are two complementary techniques to achieve the reduction of query processing cost in data warehousing design and development (Bellatreche, 2006).

FUTURE TRENDS

Currently, data warehousing is largely applied in customer relationship management (CRM). However, there are up to date no agreed upon standardized rules for how to design a data warehouse to support CRM and a taxonomy of CRM analyses needs to be developed to determine factors that affect design decisions for CRM data warehouse (Cunningham et al., 2006).

In data modeling area, to develop a more general solution for modeling data warehouse current ER model and dimensional model need to be extended to the next level to combine the simplicity of the dimensional model and the efficiency of the ER model with the support of object oriented concepts.

CONCLUSION

Several data warehousing development and design methodologies have been reviewed and discussed. Data warehouse data model differentiates itself from ER model with an orientation toward specific business purposes. It benefits an enterprise greater if the CIF and MD architectures are both considered in the design of a data warehouse. Some of the methodologies have been practiced in the real world and accepted by today's businesses. Yet new challenging methodologies, particularly in data modeling and models for physical data warehousing design, such as the metric-driven methodology, need to be further researched and developed.

KEY TERMS

Dimensions: They are the perspectives or entities with respect to which an organization wants to keep records (Han & Kamber, 2006, p. 110).

Dimensional Model: A model containing a central fact table and a set of surrounding dimension tables, each corresponding to one of the components or dimensions of the fact table.

Entity-Relationship Data Model: A model that represents database schema as a set of entities and the relationships among them.

Fact Table: The central table in a star schema, containing the names of the facts, or measures, as well as keys to each of the related dimension tables.

Metric-Drive Design: A data warehousing design approach which begins by defining key business processes that need to be measured and tracked over time. Then they are modeled in a dimensional model.

Parallel Processing: The allocation of the operating system's processing load across several processors (Singh, 1998, p. 209).

Star Schema: A modeling diagram which contains a large central table (fact table) and a set of smaller attendant tables (dimension tables) each represented by only one table with a set of attributes.

Decision Making in Intelligent Agents

INTRODUCTION

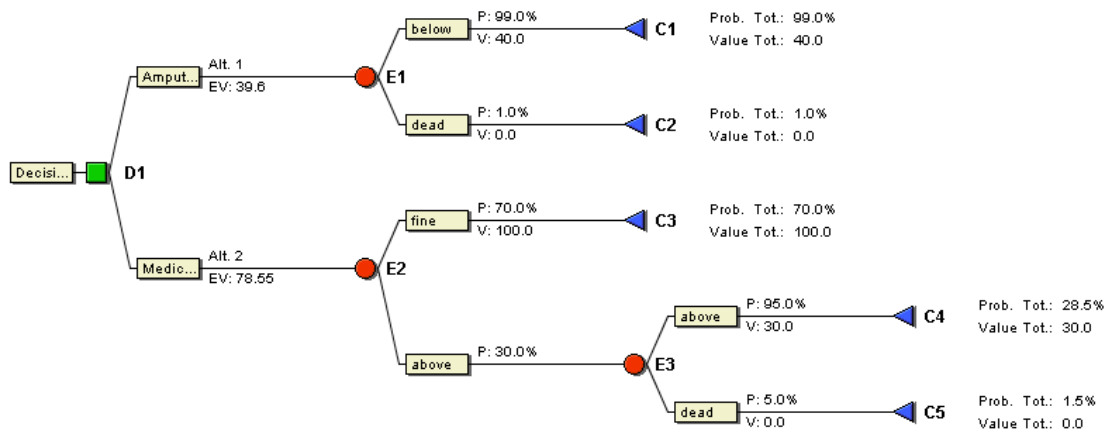

There are several ways of building complex distributed software systems, for example in the form of software agents. But regardless of the form, there are some common problems having to do with specification contra execution. One of the problems is the inherent dynamics in the environment many systems are exposed to. The properties of the environment are not known with any precision at the time of construction. This renders a specification of the system incomplete by definition. A traditional **software agent** is only prepared to handle situations conceived of and implemented at compile-time. Even though it can operate in varying contexts, its decision making abilities are static. One remedy is to prepare the distributed components for a truly dynamic environment, i.e. an environment with changing and somewhat unpredictable conditions. A rational **software agent** needs both a representation of a decision problem at hand and means for evaluation. AI has traditionally addressed some parts of this problem such as representation and reasoning, but has hitherto to a lesser degree addressed the decision making abilities of independent distributed software components (Ekenberg, 2000a, 2000b). Such decision making often has to be carried out under severe uncertainty regarding several parameters. Thus, methods for independent **decision making** components should be able to handle uncertainties on the probabilities and utilities involved. They have mostly been studied as means of representation, but are now being developed into functional theories of decision making suitable for dynamic use by software agents and other dynamic distributed components. Such a functional theory will also benefit analytical decision support systems intended to aid humans in their decision making. Thus, the generic term *agent* below stands for a dynamic software component as well as a human or a group of humans assisted by intelligent software.

BACKGROUND

Ramsey (1926/78) was the first to suggest a theory that integrated ideas on subjective probability and utility in presenting (informally) a general set of axioms for preference comparisons between acts with uncertain outcomes (probabilistic decisions). von Neumann and Morgenstern (1947) established the foundations for a modern theory of utility. They stated a set of axioms that they deemed reasonable to a rational decision-maker (such as an agent), and demonstrated that the agent should prefer the alternative with the highest expected utility, given that she acted in accordance with the axioms. This is the principle of maximizing the **expected utility**. Savage (1954/72) published a thorough treatment of a complete theory of subjective expected utility. Savage, von Neumann, and others structured decision analysis by proposing reasonable principles governing decisions and by constructing a theory out of them. In other words, they (and later many others) formulated a set of axioms meant to justify their particular attitude towards the utility principle, cf., e.g., Herstein and Milnor (1953), Suppes (1956), Jeffrey (1965/83), and Luce and Krantz (1971). In classical **decision analysis**, of the types suggested by Savage and others, a widespread opinion is that utility theory captures the concept of rationality.

After Raiffa (1968), probabilistic decision models are nowadays often given a tree representation (see Fig. 1). A **decision tree** consists of a root, representing a decision, a set of event nodes, representing some kind of uncertainty and consequence nodes, representing possible final outcomes. In the figure, the decision is a square, the events are circles, and final consequences are triangles. Events unfold from left to right, until final consequences are reached. There may also be more than one decision to make, in which case the sub-decisions are made before the main decision.

Figure 1. Decision tree

In decision trees, probability distributions are assigned in the form of weights (numbers) in the probability nodes as measures of the uncertainties involved. Obviously, such a numerically precise approach puts heavy demands on the input capability of the agent. The shortcomings of this representation are many, and have to be compensated for, see, e.g., (Ekenberg, 2000a). Among other things, the question has been raised whether people are capable of providing the input information that utility theory requires (cf., e.g., (Fischhoff et al., 1983)). For instance, most people cannot clearly distinguish between probabilities ranging roughly from 0.3 to 0.7 (Shapira, 1995). Similar problems arise in the case of artificial agents, since utility-based artificial agents usually base their reasoning on human assessments, for instance in the form of induced preference functions. The so-called reactive agents, for which this does not hold true, have not been put to use in dynamic domains involving uncertainty (cf., e.g., (Russell & Norvig, 1995)). Furthermore, even if an agent would be able to discriminate between different probabilities, very often complete, adequate, and precise information is missing.

Consequently, during recent years of rather intense research activities several alternative approaches have emerged. In particular, first-order approaches, i.e., based on sets of probability measures, upper and lower probabilities, and **interval probabilities**, have prevailed. A main class of such models has been focused on expressing probabilities in terms of intervals. In 1953, the concept of capacities was introduced (Choquet, 1953/54). This representation approach was further

developed in (Huber, 1973, Huber & Strassen, 1973). Capacities have subsequently been used for modelling imprecise probabilities as intervals (capacities of order 2 (Denneberg, 1994)). Since the beginning of the 1960s the use of **first-order** (interval-valued) probability functions, by means of classes of probability measures, has been integrated in classical probability theory by, e.g., Smith (1961) and Good (1962). Similarly, Dempster (1967) investigated a framework for modelling upper and lower probabilities, which was further developed by Shafer (1976), where a representation of belief in states or events was provided. Within the AI community the Dempster-Shafer approach has received a good deal of attention. However, their formalism seems to be too strong to be an adequate representation of belief (Weichselberger & Pöhlman, 1990).

Other representations in terms of upper and lower probabilities have been proposed by, i.a., Hodges and Lehmann (1952), Hurwicz (1951), Wald (1950), Kyburg (1961), Levi (1974, 1980), Walley (1991), Danielson and Ekenberg (1998, 2007), and Ekenberg et al. (2001). Upper and lower previsions have also been investigated by various authors. For instance, Shafer et al. (2003) suggests a theory for how to understand subjective probability estimates based on Walley (1991). A few approaches have also been based on logic, e.g., Nilsson (1986). He develops methods for dealing with sentences involving upper and lower probabilities. This kind of approaches has been pursued further by, among others, Wilson (1999).

SECOND-ORDER REPRESENTATIONS

A common characteristic of the first-order representations above is that they typically do not include all of the strong axioms of probability theory and thus they do not require an agent to model and evaluate a decision situation using precise probability (and, in some cases, value) estimates. An advantage of representations using upper and lower probabilities is that they do not require taking probability distributions into consideration. On the other hand, it is then often difficult to devise a reasonable decision rule that finds an admissible alternative out of a set of alternatives and at the same time fully reflects the intentions of an agent (or its owner). Since the probabilities and values are represented by intervals, the expected value range of an alternative will also be an interval. In effect, the procedure retains all alternatives with overlapping expected utility intervals, even if the overlap is very small. Furthermore, they do not admit for discrimination between different beliefs in different values within the intervals.

All of these representations face the same trade-off. **Zero-order** approaches (i.e. fixed numbers representing probability and utility assessments) require unreasonable precision in the representation of input data. Even though the evaluation and discrimination between alternatives becomes simple, the results are often not a good representative of the problem and sensitivity analyses are hard to carry out for more than a few parameters at a time. **First-order** approaches (e.g. intervals) offer a remedy to the representation problem by allowing imprecision in the representation of probability and utility assessments such as intervals, reflecting the uncertainty inherent in most real-life decision problems faced by agents. But this permissibility opens up a can of worms in the sense that evaluation and discrimination becomes much harder because of overlap in the evaluation results of different options for the agent, i.e. the worst case for one alternative is no better than the best case for another alternative or vice versa, rendering a total ranking order between the alternatives impossible to achieve. The trade-off between realistic representation and discriminative power has not been solved within the above paradigms. For a solution, one must look at **second-order** approaches allowing both imprecision in representation and power of admissible discrimination.

Approaches for extending the interval representation using distributions over classes of probability

and value measures have been developed into various hierarchical models, such as second-order probability theory (Gärdenfors & Sahlin, 1982, 1983, Ekenberg & Thorbiörnson, 2001, Ekenberg et al., 2005). Gärdenfors and Sahlin consider global distributions of beliefs, but restrict themselves to interval representations and only to probabilities, not utilities. Other limitations are that they neither investigate the relation between global and local distributions, nor do they introduce methods for determining the consistency of user-asserted sentences. The same applies to Hodges and Lehmann (1952), Hurwicz (1951), and Wald (1950). Some more specialized approaches have recently been suggested, such as (Jaffray, 1999), (Nau, 2002), and (Utkin & Augustin, 2003). In general, very few have addressed the problems of computational complexity when solving decision problems involving such estimates. Needless to say, it is important in dynamic agents to be able to determine, in a reasonably short time, how various evaluative principles rank the given options in a decision situation.

Ekenberg et al. (2006) and Danielson et al. (2007) provide a framework for how second-order representation can be systematically utilized to put belief information into use in order to efficiently discriminate between alternatives that evaluate into overlapping expected utility intervals when using first-order interval evaluations. The belief information is in the form of a joint belief distribution, specified as marginal belief distributions projected on each parameter. It is shown that regardless of the form of belief distributions over the originating intervals, the distributions resulting from multiplications and additions have forms very different from their components. This warp of resulting belief demonstrates that analyses using only first-order information such as upper and lower bounds are not taking all available information into account. The method is based on the agent's belief in different parts of the intervals, expressed or implied, being taken into consideration. It can be said to represent the beliefs in various sub-parts of the feasible intervals. As a result, total lack of overlap is not required for successful discrimination between alternatives. Rather, an overlap by interval parts carrying little belief mass, i.e. representing a small part of the agent's belief, is allowed. Then, the non-overlapping parts can be thought of as being the core of the agent's appreciation of the decision situation, thus allowing discrimination.

There are essentially three ways of evaluating (i.e. making a decision in) a second-order agent decision problem. The first way (centroid analysis) is to use the centroid as the best single-point representative of the distributions. The centroid is additive and multiplicative. Thus, the centroid of the distribution of expected utility is the expected utility of the centroids of the projections. A centroid analysis gives a good overview of a decision situation. The second way (contraction analysis) is to use the **centroid** as a focal point (contraction point) towards which the intervals are decreased while studying the overlap in first-order expected utility intervals. The third way (distribution analysis) is more elaborated, involving the analysis of the resulting distributions of expected utility and calculating the fraction of belief overlapping between alternatives being evaluated.

FUTURE TRENDS

During recent years, the activities within the area of imprecise probabilities have increased substantially (IPP) and special conferences (ISIPTA) and journals (IJAR) are now dedicated to this theme. Second-order theories will in the future be fully developed into functional theories of decision making suitable for dynamic use by distributed software components. Algorithms for the efficient evaluation by agents using at least the first two ways of analyses above will be developed.

CONCLUSION

In this article, we discuss various approaches to probabilistic decision making in agents. We point out that theories incorporating second-order belief can provide more powerful discrimination to the agent (software agent or human being) when handling aggregations of interval representations, such as in decision trees or probabilistic networks, and that interval estimates (upper and lower bounds) in themselves are not complete. This applies to all kinds of decision trees and probabilistic networks since they all use multiplications for the evaluations. The key idea is to use the information available in efficient evaluation of decision structures. Using only interval estimates often does not provide enough discrimination power for the agent to generate a preference order among alternatives considered.

Second-order methods are not just nice theories, but should be taken into account to provide efficient decision methods for agents, in particular when handling aggregations of imprecise representations as is the case in decision trees or probabilistic networks.

KEY TERMS

Admissible Alternative: Given a decision tree and two alternatives A_i and A_j , A_i is at least as good as A_j iff $E(A_i) - E(A_j) > 0$, where $E(A_i)$ is the expected value of A_i , for all consistent variable assignments for the probabilities and values. A_i is better than A_j iff A_i is at least as good as A_j and $E(A_i) - E(A_j) > 0$ for some consistent variable assignments for the probabilities and values. A_i is admissible iff no other A_j is better.

Centroid: Given a belief distribution F over a cube B , the centroid F_c of F is

$$F_c = \int_B x F(x) dV_B(x),$$

where V_B is some k -dimensional Lebesgue measure on B .

Decision Tree: A decision tree consists of a root node, representing a decision, a set of intermediate (event) nodes, representing some kind of uncertainty and consequence nodes, representing possible final

outcomes. Usually, probability distributions are assigned in the form of weights in the probability nodes as measures of the uncertainties involved.

Expected Value: Given a decision tree with r alternatives A_i for $i = 1, \dots, r$, the expression

$$E(A_i) = \sum_{i_1=1}^{n_0} p_{ii_1} \sum_{i_2=1}^{n_{i_1}} p_{ii_1 i_2} \cdots \sum_{i_{m-1}=1}^{n_{i_{m-2}}} p_{ii_1 i_2 \cdots i_{m-1}} \sum_{i_m=1}^{n_{i_{m-1}}} p_{ii_1 i_2 \cdots i_{m-1} i_m} v_{ii_1 i_2 \cdots i_{m-1} i_m}$$

where $p_{ii_1 \dots i_m}$, $j \in (1, \dots, m)$, denote probability variables and $v_{ii_1 \dots i_m}$ denote value variables, is the *expected value* of alternative A_i .

Joint Belief Distribution: Let a unit cube be represented by $B = (b_1, \dots, b_k)$. By a joint belief distribution over B , we mean a positive distribution F defined on the unit cube B such that

$$\int_B F(x) dV_B(x) = 1,$$

where V_B is some k -dimensional Lebesgue measure on B .

Marginal Belief Distribution: Let a unit cube:

$B = (b_1, \dots, b_k)$ and $F \in BD(B)$ be given. Furthermore, let $B_i^- = (b_1, \dots, b_{i-1}, b_{i+1}, \dots, b_k)$. Then

$$f_i(x_i) = \int_{B_i^-} F(x) dV_{B_i^-}(x)$$

is a marginal belief distribution over the axis b_i .

Projection: Let $B = (b_1, \dots, b_k)$ and $A = (b_{i_1}, \dots, b_{i_s})$:

$i_j \in \{1, \dots, k\}$ be unit cubes. Furthermore, let $F \in BD(B)$, and let

$$f_A(x) = \int_{B-A} F(x) dV_{B-A}(x).$$

Then f_A is the *projection of F on A* . A projection of a belief distribution is also a belief distribution.

Decision Tree Applications for Data Modelling

INTRODUCTION

Many organisations, nowadays, have developed their own databases, in which a large amount of valuable information, e.g., customers' personal profiles, is stored. Such information plays an important role in organisations' development processes as it can help them gain a better understanding of customers' needs. To effectively extract such information and identify hidden relationships, there is a need to employ intelligent techniques, for example, data mining.

Data mining is a process of knowledge discovery (Roiger & Geatz, 2003). There are a wide range of data mining techniques, one of which is decision trees. Decision trees, which can be used for the purposes of classifications and predictions, are a tool to support decision making (Lee et al., 2007). As a decision tree can accurately classify data and make effective predictions, it has already been employed for data analyses in many application domains. In this paper, we attempt to provide an overview of the applications that decision trees can support. In particular, we focus on business management, engineering, and health-care management.

The structure of the paper is as follows. Firstly, Section 2 provides the theoretical background of decision trees. Section 3 then moves to discuss the applications that decision trees can support, with an emphasis on business management, engineering, and health-care management. For each application, how decision trees can help identify hidden relationships is described. Subsequently, Section 4 provides a critical discussion

of limitations and identifies potential directions for future research. Finally, Section 5 presents the conclusions of the paper.

BACKGROUND

Decision trees are one of the most widely used classification and prediction tools. This is probably because the knowledge discovered by a decision tree is illustrated in a hierarchical structure, with which the discovered knowledge can easily be understood by individuals even though they are not experts in data mining (Chang et al., 2007). A decision tree model can be created in several ways using existing decision tree algorithms. In order to effectively adopt such algorithms, there is a need to have a solid understanding of the processes of creating a decision tree model and to identify suitability of the decision tree algorithms used. These issues are described in subsections below.

Processes of Model Development

A common way to create a decision tree model is to employ a top-down, recursive, and divide-and-conquer approach (Greene & Smith, 1993). Such a modelling approach enables the most significant attribute to be located at the top level as a root node and the least significant attributes to be located at the bottom level as leave nodes (Chien et al., 2007). Each path between the root node and the leave node can be interpreted as an 'if-then' rule, which can be used for making predictions (Chien et al., 2007; Kumar & Ravi, 2007).

To create a decision tree model on the basis of the above-mentioned approach, the modelling processes can be divided into three stages, which are: (1) tree growing, (2) tree pruning, and (3) tree selection.

Tree Growing

The initial stage of creating a decision tree model is tree growing, which includes two steps: tree merging and tree splitting. At the beginning, the non-significant predictor categorises and the significant categories within a dataset are grouped together (tree merging). As the tree grows, impurities within the model will increase. Since the existence of impurities may result in reducing the accuracy of the model, there is a need to purify the tree. One possible way to do it is to remove the impurities into different leaves and ramifications (tree splitting) (Chang, 2007).

Tree Pruning

Tree pruning, which is the key elements of the second stage, is to remove irrelevant splitting nodes (Kirkos et al., 2007). The removal of irrelevant nodes can help reduce the chance of creating an over-fitting tree. Such a procedure is particularly useful because an over-fitting tree model may result in misclassifying data in real world applications (Breiman et al., 1984).

Tree Selection

The final stage of developing a decision tree model is tree selection. At this stage, the created decision tree model will be evaluated by either using cross-validation or a testing dataset (Breiman *et al.*, 1984). This stage is essential as it can reduce the chances of misclassifying data in real world applications, and consequently, minimise the cost of developing further applications.

Suitability of Decision Tree Algorithms

A review of existing literature shows that the most widely used decision tree algorithms include the Iterative Dichotomiser 3 (ID3) algorithm, the C4.5 algorithm, the Chi-squared Automatic Interactive Detector (CHAID) algorithm, and the Classification and Regression Tree (CART) algorithm. Amongst these algorithms, there are some differences, one of which is the capability of

modelling different types of data. As a dataset may be constructed by different types of data, e.g., categorical data, numerical data, or the combination of both, there is a need to use a suitable decision tree algorithm which can support the particular type of data used in the dataset. All of the above-mentioned algorithms can support the modelling of categorical data whilst only the C4.5 algorithm and the CART algorithm can be used for the modelling of numerical data (see Table 1). This difference can also be used as a guideline for the selection of a suitable decision tree algorithm. The other difference amongst these algorithms is the process of model development, especially at the stages of tree growing and tree pruning. In terms of the former, the ID3 and C4.5 algorithms split a tree model into as many ramifications as necessary whereas the CART algorithm can only support binary splits. Regarding the latter, the pruning mechanisms located within the C4.5 and CART algorithms support the removal of insignificant nodes and ramifications but the CHAID algorithm hinders the tree growing process before the training data is being overused (see Table 1).

DECISION TREE APPLICATIONS

Business Management

In the past decades, many organizations had created their own databases to enhance their customer services. Decision trees are a possible way to extract useful information from databases and they have already been employed in many applications in the domain of business and management. In particular, decision tree modelling is widely used in customer relationship management and fraud detection, which are presented in subsections below.

Customer Relationship Management

A frequently used approach to manage customers' relationships is to investigate how individuals access online services. Such an investigation is mainly performed by collecting and analyzing individuals' usage data and then providing recommendations based on the extracted information. Lee et al. (2007) apply decision trees to investigate the relationships between the customers' needs and preferences and the success of online shopping. In their study, the frequency of us-

ing online shopping is used as a label to classify users into two categories: (a) users who rarely used online shopping and (b) users who frequently used online shopping. In terms of the former, the model suggests that the time customers need to spend in a transaction and how urgent customers need to purchase a product are the most important factors which need to be considered. With respect to the latter, the created model indicates that price and the degree of human resources involved (e.g. the requirements of contacts with the employees of the company in having services) are the most important factors. The created decision trees also suggest that the success of an online shopping highly depends on the frequency of customers' purchases and the price of the products. Findings discovered by decision trees are useful for understanding their customers' needs and preferences.

Fraudulent Statement Detection

Another widely used business application is the detection of Fraudulent Financial Statements (FFS). Such an application is particularly important because the existence of FFS may result in reducing the government's tax income (Spathis *et al.*, 2003). A traditional way to identify FFS is to employ statistical methods. However, it is difficult to discover all hidden information due to the necessity of making a huge number of assumptions and predefining the relationships among the large number of variables in a financial statement.

Previous research has proved that creating a decision tree is a possible way to address this issue as it can consider all variables during the model development process. Kirkos *et al.* (2007) have created a decision tree model to identify and detect FFS. In their study, 76 Greek manufacturing firms have been selected and their published financial statements, including balance sheets and income statements, have been collected for modelling purposes. The created tree model shows that all non-fraud cases and 92% of the fraud cases have been correctly classified. Such a finding indicates that decision trees can make a significant contribution for the detection of FFS due to a highly accurate rate.

Engineering

The other important application domain that decision trees can support is engineering. In particular, decision trees are widely used in energy consumption and fault diagnosis, which are described in subsections below.

Energy Consumption

Energy consumption concerns how much electricity has been used by individuals. The investigation of energy consumption becomes an important issue as it helps utility companies identify the amount of energy needed. Although many existing methods can be used for the investigation of energy consumption, decision trees appear to be preferred. This is due to the fact that

Table 1. Characteristics of different decision tree algorithms

| Decision tree algorithms | Data types | Numerical data splitting method | Possible tool |
|-------------------------------------|------------------------|---------------------------------|-----------------------------------|
| CHAID (Kass, 1980) | Categorical | N/A | SPSS Answer Tree (SPSS Inc, 2007) |
| ID3 (Quinlan, 1986) | Categorical | No restrictions | WEKA (Ian and Eibe, 2005) |
| C4.5 (Quinlan, 1993) | Categorical, numerical | No restrictions | WEKA (Ian and Eibe, 2005) |
| CART (Breiman <i>et al.</i> , 1984) | Categorical, numerical | Binary splits | CART 5.0 (Salford Systems, 2004) |

a hierarchical structure provided by decision trees is useful to present the deep level of information and insight. For instance, Tso and Yau (2007) create a decision tree model to identify the relationships between a household and its electricity consumptions in Hong Kong. Findings from their tree model illustrate that the number of household members are the most determinant factor of energy consumption in summer, and both the number of air-conditioner and the size of a flat are the second most important factors. In addition to such findings, their tree model identifies that a household with four or more members with a flat size larger than 817ft² is the highest electricity consumption group. On the other hand, households which have less than four family members and without air-conditioners are the smallest electricity consumption group. Such findings from decision trees not only provide a deeper insight of the electricity consumptions within an area but also give guidelines to electricity companies about the right time they need to generate more electricity.

Fault Diagnosis

Another widely used application in the engineering domain is the detection of faults, especially in the identification of a faulty bearing in rotary machineries. This is probably because a bearing is one of the most important components that directly influences the operation of a rotary machine. To detect the existence of a faulty bearing, engineers tend to measure the vibration and acoustic emission (AE) signals emanated from the rotary machine. However, the measurement involves a number of variables, some of which may be less relevant to the investigation. Decision trees are a possible tool to remove such irrelevant variables as they can be used for the purposes of feature selection. Sugumaran and Ramachandran (2007) create a decision tree model to identify the features that may significantly affect the investigation of a faulty bearing. Through feature selection, three attributes were chosen to discriminate the faulty conditions of a bearing, i.e., the minimum value of the vibration signal, the standard deviation of the vibration signal, and kurtosis. The chosen attributes, subsequently, were used for creating another decision tree model. Evaluations from this model show that more than 95% of the testing dataset has been correctly classified. Such a highly accurate rate suggests that the removal of insignificant attributes within a dataset is another contribution of decision trees.

Healthcare Management

As decision tree modelling can be used for making predictions, there are an increasing number of studies that investigate to use decision trees in health-care management. For instance, Chang (2007) has developed a decision tree model on the basis of 516 pieces of data to explore the hidden knowledge located within the medical history of developmentally-delayed children. The created model identifies that the majority of illnesses will result in delays in cognitive development, language development, and motor development, of which accuracies are 77.3%, 97.8%, and 88.6% respectively. Such findings can result in assisting healthcare professional to have an early intervention on developmentally-delayed children so as to help them catch up their normal peers in their development and growth. Another example of health-care management can be found in Delen *et al.* (2005). In their study, a decision tree is created to predict the survivability of breast cancer patients. The classification accuracy is 93.6% in their decision tree. This classification rate indicates that the created tree is highly accurate for predicting the survivability of breast cancer patients. These studies suggest that decision tree is a useful tool to discover and explore hidden information in health-care management.

FUTURE TRENDS

The applications domains mentioned above demonstrate that decision tree is a very useful tool for data analyses. However, there are still many limitations which we need to be aware of and addressed in future works.

Reliability of Findings

Although decision tree is a powerful tool for data analyses, it seems that some data are misclassified in the decision tree models. A possible way to address this issue is to exploit the extracted knowledge by human-computer collaboration. In other words, experts from different domains use their domain knowledge to filter findings from the created model. By doing so, the irrelevant findings can manually be removed. However, the drawback of employing such a method is the necessity of large investment as it involves the cost and time of experts from different domains.

Suitability of Algorithms

As described in Section 2.2, the development of a decision tree model involves the selection of an appropriate decision tree algorithm. In addition to taking into account the type of data being modelled, there is a need to consider the effectiveness of the algorithms. Another possible direction for future research is to compare the effectiveness of various algorithms and identify the strengths and weaknesses of each algorithm for different types of applications. In addition, it would be interesting for future research to conduct comparisons between decision tree algorithms and other types of classification algorithms. By doing so, guidelines for the selection of suitable decision tree algorithms for different types of applications can be generated.

CONCLUSION

The main objective of this paper is to help readers get an overall picture of decision trees by introducing its applications in different domains. To achieve this objective, this paper has provided an overview of the applications of decision tree modelling in business management, engineering, and health-care management domains. In each application domain, the benefits of creating a decision tree model for the purposes of analyzing data and making predictions have been identified. Such benefits include: (1) the capability to accurately discover hidden relationships between variables, (2) the presentation of knowledge in a deep level of understanding and insight on the basis of its hierarchical structure, and (3) the capability of removing insignificant attributes within a dataset.

Three application domains have been studied in this paper, but it ought to be noted that decision trees can also be applied in other application domains, e.g. bioinformatics and psychology. These application domains should also be examined. The findings of such studies can subsequently be integrated into those of this study so that a complete framework for implementing decision trees models can be created. Such a framework would be useful to enhance the depth and breadth of the knowledge of decision tree models.

KEY TERMS

Attributes: Pre-defined variables in a dataset.

Classification: An allocation of items or objects to classes or categories according to their features.

Customer Relationship Management: A dynamic process to manage the relationships between a company and her customers, including collecting, storing and analysing customers' information.

Data Mining: Also known as knowledge discovery in database (KDD), which is a process of knowledge discovery by analysing data and extracting information from a dataset using machine learning techniques.

Decision Tree: A predictive model which can be visualized in a hierarchical structure using leaves and ramifications.

Decision Tree Modelling: The process of creating a decision tree model.

Fault Diagnosis: An action of identifying a malfunctioning system based on observing its behaviour.

Fraud Detection Management: The detection of frauds, especially in those existing in financial statements or business transactions so as to reduce the risk of loss.

Healthcare Management: The act of preventing, treating and managing illness, including the preservation of mental and physical problems through the services provided by health professionals.

Prediction: A statement or a claim that a particular event will happen in the future.

The Dempster–Shafer Theory

Malcolm J. Beynon
Cardiff University, UK

INTRODUCTION

The initial work introducing Dempster-Shafer (D-S) theory is found in Dempster (1967) and Shafer (1976). Since its introduction the very name causes confusion, a more general term often used is belief functions (both used intermittently here). Nguyen (1978) points out, soon after its introduction, that the rudiments of D-S theory can be considered through distributions of random sets. More furtive comparison has been with the traditional Bayesian theory, where D-S theory has been considered a generalisation of it (Schubert, 1994). Cobb and Shenoy (2003) direct its attention to the comparison of D-S theory and the Bayesian formalisation. Their conclusions are that they have the same expressive power, but that one technique cannot simply take the role of the other.

The association with artificial intelligence (AI) is clearly outlined in Smets (1990), who at the time, acknowledged the AI community has started to show interest for what they call the Dempster-Shafer model. It is of interest that even then, they highlight that there is confusion on what type of version of D-S theory is considered. D-S theory was employed in an event driven integration reasoning scheme in Xia *et al.* (1997), associated with automated route planning, which they view as a very important branch in applications of AI. Liu (1999) investigated Gaussian belief functions and specifically considered their proposed computation scheme and its potential usage in AI and statistics. Huang and Lees (2005) apply a D-S theory model in natural-resource classification, comparing with it with two other AI models.

Wadsworth and Hall (2007) considered D-S theory in a combination with other techniques to investigate site-specific critical loads for conservation agencies. Pertinently, they outline its positioning with respect to AI (p. 400);

The approach was developed in the AI (artificial intelligence) community in an attempt to develop systems that could reason in a more human manner and par-

ticularly the ability of human experts to “diagnose” situations with limited information.

This statement is pertinent here, since emphasis within the examples later given is more towards the general human decision making problem and the handling of ignorance in AI. Dempster and Kong (1988) investigated how D-S theory fits in with being an artificial analogy for human reasoning under uncertainty.

An example problem is considered, the murder of Mr. White, where witness evidence is used to classify the belief in the identification of an assassin from considered suspects. The numerical analyses presented exposit a role played by D-S theory, including the different ways it can act on incomplete knowledge.

BACKGROUND

The background section to this article covers the basic formulations of D-S theory, as well as certain developments. Formally, D-S theory is based on a finite set of p elements $\Theta = \{s_1, s_2, \dots, s_p\}$, called a frame of discernment. A *mass value* is a function $m: 2^\Theta \rightarrow [0, 1]$ such that $m(\emptyset) = 0$ (\emptyset - the empty set) and:

$$\sum_{s \in 2^\Theta} m(s) = 1$$

(2^Θ - the power set of Θ). Any proper subset s of the frame of discernment Θ , for which $m(s)$ is non-zero, is called a focal element and represents the exact belief in the proposition depicted by s . The notion of a proposition here being the collection of the hypotheses represented by the elements in a focal element.

In the original formulation of D-S theory, from a single piece of evidence all assigned mass values sum to unity and there is no belief in the empty set. In the case of the Transferable Belief Model (TBM), a fundamental development on the original D-S theory (see Smets and Kennes, 1994), a non-zero mass value

can be assigned to the empty set allowing $m(\emptyset) \geq 0$. The set of mass values associated with a single piece of evidence is called a *body of evidence* (BOE), often denoted $m(\cdot)$. The mass value $m(\Theta)$ assigned to the frame of discernment Θ is considered the amount of ignorance within the BOE, since it represents the level of exact belief that cannot be discerned to any proper subsets of Θ .

D-S theory also provides a method to combine the BOE from different pieces of evidence, using Dempster's rule of combination. This rule assumes these pieces of evidence are independent, then the function $(m_1 \oplus m_2): 2^\Theta \rightarrow [0, 1]$, defined by:

$$(m_1 \oplus m_2)(x) = \begin{cases} 0 & x = \emptyset \\ \frac{\sum_{s_1 \cap s_2 = x} m_1(s_1)m_2(s_2)}{1 - \sum_{s_1 \cap s_2 = \emptyset} m_1(s_1)m_2(s_2)} & x \neq \emptyset \end{cases} \quad (1)$$

is a mass value, where s_1 and s_2 are focal elements from the BOEs, $m_1(\cdot)$ and $m_2(\cdot)$, respectively. The denominator part of the combination expression includes:

$$\sum_{s_1 \cap s_2 = \emptyset} m_1(s_1)m_2(s_2)$$

that measures the level of conflict in the combination process (Murphy, 2000). It is the existence of the denominator part in this combination rule that separates D-S theory (includes it) from TBM (excludes it). Benouhiba and Nigro (2006) view this difference as whether considering the conflict mass:

$$\left(\sum_{s_1 \cap s_2 = \emptyset} m_1(s_1)m_2(s_2) \right)$$

as a further form of ignorance mass is an acceptable point of view.

D-S theory, along with TBM, also differs to the Bayesian approach in that it does not necessarily produce

final results. Moreover, partial answers are present in the final BOE produced (through the combination of evidence), including focal elements with more than one element, unlike the Bayesian approach where probabilities on only individual elements would be accrued. This restriction of the Bayesian approach to consider singleton elements is clearly understood through the 'Principle of insufficient Reason', see Beynon *et al.* (2000) and Beynon (2002, 2005).

To enable final results to be created with D-S theory, a number of concomitant functions exist with D-S theory, including;

i) The Belief function,

$$\text{Bel}(s_i) = \sum_{s_j \subseteq s_i} m(s_j)$$

for all $s_i \subseteq \Theta$, representing the confidence that a proposition y lies in s_i or any subset of s_i ,

ii) The Plausibility function,

$$\text{Pls}(s_i) = \sum_{s_j \cap s_i \neq \emptyset} m(s_j)$$

for all $s_i \subseteq \Theta$, represents the extent to which we fail to disbelieve s_i ,

iii) The Pignistic function (see Smets and Kennes, 1994),

$$\text{BetP}(s_i) = \sum_{s_j \subseteq \Theta, s_j \neq \emptyset} m(s_j) \frac{|s_i \cap s_j|}{|s_j|},$$

for all $s_i \subseteq \Theta$, represents the extent to which we fail to disbelieve s_i .

From the definitions given above, the Belief function is cautious of the ignorance incumbent in the evidence, where as the Plausibility function is more inclusive of its presence. The Pignistic function acts more like a probability function, partitioning levels of exact belief (mass) amongst the elements of the focal element it is associated with.

The Dempster-Shafer Theory

A non-specificity measure $N(m(\cdot))$ within D-S theory was introduced by Dubois and Prade (1985), the formula is defined as,

$$N(m(\cdot)) = \sum_{s_j \in 2^\Theta} m(s_j) \log_2 |s_j|,$$

where $|s_j|$ is the number of elements in the focal element s_j . Hence, $N(m(\cdot))$ is considered the weighted average of the focal elements, with $m(\cdot)$ the degree of evidence focusing on s_j , while $\log_2 |s_j|$ indicates the lack of specificity of this evidential claim. The general range of this measure is $[0, \log_2 |\Theta|]$ (given in Klir and Wierman, 1998), where $|\Theta|$ is the number of elements in the frame of discernment Θ .

Main Thrust

The main thrust of this article is an exposition of the utilisation of D-S theory. The small example problem considered here relates to the assassination of Mr White, many derivatives of this example exist. An adaptation of a version of this problem given in Smets (1990) is discussed, more numerical based here, which allows interpretation with D-S theory and its development TBM to be made.

There are three individuals who are suspects for the murder of Mr. White, namely, Henry, Tom and Sarah, within D-S theory they make up the frame of discernment, $\Theta = \{\text{Henry, Tom, Sarah}\}$. There are two witnesses who have information regarding the murder of Mr. White;

Witness 1, is 80% sure that the murderer was a man, it follows, the concomitant body of evidence (BOE), defined $m_1(\cdot)$, includes $m_1(\{\text{Henry, Tom}\}) = 0.8$. Since we know nothing about the remaining mass value it is considered ignorance, and allocated to Θ , hence $m_1(\{\text{Henry, Tom, Sarah}\}) = 0.2 (= m_1(\Theta))$.

Witness 2, is 60% confident that Henry was leaving on a jet plane when the murder occurred, so a BOE defined $m_2(\cdot)$ includes, $m_2(\{\text{Tom, Sarah}\}) = 0.6$ and $m_2(\{\text{Henry, Tom, Sarah}\}) = 0.4$.

The aggregation of these two sources of information (evidence from the two witnesses), using Dempster's combination rule (1), is based on the intersection and

Table 1. Intermediate combination of BOEs, $m_1(\cdot)$ and $m_2(\cdot)$

| | | |
|-----------------------------------|-------------------------------|-------------------------------|
| $m_1(\cdot) \setminus m_2(\cdot)$ | $\{\text{Tom, Sarah}\}, 0.6$ | $\Theta, 0.4$ |
| $\{\text{Henry, Tom}\}, 0.8$ | $\{\text{Tom}\}, 0.48$ | $\{\text{Henry, Tom}\}, 0.32$ |
| $\Theta, 0.2$ | $\{\text{Tom, Sarah}\}, 0.12$ | $\Theta, 0.08$ |

multiplication of the focal elements and mass values from the BOEs, $m_1(\cdot)$ and $m_2(\cdot)$, see Table 1.

In Table 1, the intersection and multiplication of the focal elements and mass values from the BOEs, $m_1(\cdot)$ and $m_2(\cdot)$ are presented. The new focal elements found are all non-empty, it follows, the level of conflict

$$\sum_{s_1 \cap s_2 = \emptyset} m_1(s_1) m_2(s_2) = 0,$$

then the resultant BOE, defined $m_3(\cdot)$, can be taken directly from the results in Table 1;

$$\begin{aligned} m_3(\{\text{Tom}\}) &= 0.48, m_3(\{\text{Henry, Tom}\}) = 0.32, \\ m_3(\{\text{Tom, Sarah}\}) &= 0.12 \\ \text{and } m_3(\{\text{Henry, Tom, Sarah}\}) &= 0.08. \end{aligned}$$

Amongst this combination of evidence ($m_3(\cdot)$), the mass value assigned to ignorance ($m_3(\{\text{Henry, Tom, Sarah}\}) = 0.08$) is less than that present in the original constituent BOEs, as expected when combining evidence using D-S theory. To further exposit the effect of the combination of evidence, the respective non-specificity values associated with BOEs shown here are calculated. For the two witnesses, with their BOEs, $m_1(\cdot)$ and $m_2(\cdot)$;

$$\begin{aligned} N(m_1(\cdot)) &= \sum_{s_j \in 2^\Theta} m_1(s_j) \log_2 |s_j| \\ &= m_1(\{\text{Henry, Tom}\}) \log_2 |\{\text{Henry, Tom}\}| \\ &\quad + m_1(\{\text{Henry, Tom, Sarah}\}) \log_2 |\{\text{Henry, Tom, Sarah}\}|, \\ &= 0.8 \times \log_2 2 + 0.2 \times \log_2 3 = 1.117, \end{aligned}$$

and $N(m_2(\cdot)) = 1.234$. The non-specificity associated with the combined is similarly calculated, found to be $N(m_3(\cdot)) = 0.567$. The values further demonstrate the

effect of the combination process, namely a level of concomitant non-specificity associated with the BOE $m_3(\cdot)$, found from the combination of the other two BOEs $m_1(\cdot)$ and $m_2(\cdot)$.

To allow a comparison of this combination process, D-S theory is used with the situation for TBM, the evidence from witness 2 is changed slightly, becoming;

Witness 2, is 60% confident that Henry and Tom were leaving on a jet plane when the murder occurred, so a BOE defined $m_2(\cdot)$ includes, $m_2(\{Sarah\}) = 0.6$ and $m_2(\{Henry, Tom, Sarah\}) = 0.4$.

The difference between the two ‘Witness 2’ statements is that, in the second statement, now Tom is also considered to be leaving on the jet plane with Henry. The new intermediate calculations when combining the evidence from the two witnesses is shown in Table 2.

In the intermediate results in Table 2, there is an occasion where the intersection of two focal elements from $m_1(\cdot)$ and $m_2(\cdot)$ results in an empty set (\emptyset). It follows,

$$\sum_{s_1 \cap s_2 = \emptyset} m_1(s_1)m_2(s_2) = 0.48,$$

giving the value, $1 - 0.48 = 0.52$, forms the denominator in the expression for the combination of this evidence (see (1)), so the resultant BOE, here defined $m_4(\cdot)$, is;

$$m_4(\{Henry, Tom\}) = 0.32/0.52 = 0.615, m_4(\{Sarah\}) = 0.231 \text{ and } m_4(\{Henry, Tom, Sarah\}) = 0.154.$$

Comparison with the results in the BOEs, $m_3(\cdot)$ and $m_4(\cdot)$, show how the mass value associated with $m_3(\{Tom\}) = 0.48$ has been spread across the three focal elements which make up the $m_4(\cdot)$ BOE.

Table 2. Intermediate combination of BOEs, $m_1(\cdot)$ and $m_2(\cdot)$, with the new ‘Witness 2’ evidence

| | | |
|-----------------------------------|-------------------|------------------------|
| $m_1(\cdot) \setminus m_2(\cdot)$ | $\{Sarah\}, 0.6$ | $\Theta, 0.4$ |
| $\{Henry, Tom\}, 0.8$ | $\emptyset, 0.48$ | $\{Henry, Tom\}, 0.32$ |
| $\Theta, 0.2$ | $\{Sarah\}, 0.12$ | $\Theta, 0.08$ |

This approach to counter the conflict possibly present when combining evidence is often viewed as not appropriate, with TBM introduced to offer a solution, hence using the second ‘Witness 2’ statement, the resultant combined BOE, defined $m_5(\cdot)$, is taken directly from Table 2;

$$m_5(\emptyset) = 0.48, m_5(\{Henry, Tom\}) = 0.32, m_5(\{Sarah\}) = 0.12 \text{ and } m_5(\{Henry, Tom, Sarah\}) = 0.08.$$

The difference between the BOEs, $m_4(\cdot)$ and $m_5(\cdot)$, is in the inclusion of the focal element $m_5(\emptyset) = 0.48$, allowed when employing TBM. Beyond the difference in the calculations made between D-S theory and TBM, the important point is what is the interpretation to the $m_5(\emptyset)$ expression in TBM. Put succinctly, following Smets (1990), $m_5(\emptyset) = 0.48$ corresponds to that amount of belief allocated to none of the three suspects, taken further it is the proposition that none of the three suspects is the murderer. Since the three individuals are only suspects, the murderer might be someone else, if the initial problem has said that one of the three individuals is the murderer then the D-S theory approach should be adhered to.

Returning to the analysis of the original witness statements, the partial results presented so far do not identify explicitly which suspect is most likely to have undertaken the murder of Mr. White. To achieve explicit results, the three measures, $Bel(s_i)$, $Pls(s_i)$ and $BetP(s_i)$ previously defined, are considered on singleton focal elements (s_i are individual suspects);

$$Bel(\{Henry\}) = \sum_{s_j \subseteq \{Henry\}} m_3(s_j) = 0.00,$$

similarly $Bel(\{Tom\}) = 0.48$ and $Bel(\{Sarah\}) = 0.00$.

$$\begin{aligned} Pls(\{Henry\}) &= \sum_{s_j \cap \{Henry\} \neq \emptyset} m_3(s_j) = m_3(\{Henry, Tom\}) + \\ & \quad m_3(\{Henry, Tom, Sarah\}), \\ &= 0.32 + 0.08 = 0.40, \end{aligned}$$

similarly, $Pls(\{Tom\}) = 1.00$ and $Pls(\{Sarah\}) = 0.20$.

$$\begin{aligned} BetP(\{Henry\}) &= \sum_{s_j \subseteq \Theta, s_j \neq \emptyset} m_3(s_j) \frac{|\{Henry\} \cap s_j|}{|s_j|}, \\ &= m_3(\{Henry, Tom\}) \frac{|\{Henry\} \cap \{Henry, Tom\}|}{|\{Henry, Tom\}|} \end{aligned}$$

$$+ m_3(\Theta) \frac{|\{\text{Henry}\} \cap \Theta|}{|\Theta|},$$

$$= 0.16 + 0.027 = 0.187,$$

similarly, $\text{BetP}(\{\text{Tom}\}) = 0.727$ and $\text{BetP}(\{\text{Sarah}\}) = 0.087$.

In this small example, all three measures identify the suspect Tom as having the most evidence purporting to them being the murderer of Mr. White.

FUTURE TRENDS

Dempster-Shafer (D-S) theory is a methodology that offers an alternative, possibly developed generality, to the assignment of frequency-based probability to events, in its case levels of subjective belief. However, the issues surrounding its position with respect to other methodologies such as the more well known Bayesian approach could be viewed as stifling its utilisation. The important point to remember when considering D-S theory is that it is a general methodology that requires subsequent pertinent utilisation when deriving nascent techniques.

Future work needs to aid in finding the position of D-S theory relative to the other methodologies. That is, unlike methodologies like fuzzy set theory, D-S theory is not able to be employed straight on top of existing techniques, to create a D-S type derivative of the technique. Such derivatives, for example, could operate on incomplete data, including when there are missing values, their reason for missing possibly due to ignorance etc.

CONCLUSION

Dempster-Shafer (D-S) theory, and its general developments, continues to form the underlying structure to an increasing number of specific techniques that attempt to solve certain problems within the context of uncertain reasoning. As mentioned in the future trends section, the difficulty with D-S theory is that it needs to be considered at the start of work at creating a new technique for analysis. It follows, articles like this which show the rudimentary workings of D-S theory allow researchers the opportunity to see its operation, and so may contribute to its further utilisation.

KEY TERMS

Belief: In Dempster-Shafer theory, the level of representing the confidence that a proposition lies in a focal element or any subset of it.

Body of Evidence: In Dempster-Shafer theory, a series of focal elements and associated mass values.

Focal Element: In Dempster-Shafer theory, a set of hypotheses with positive mass value in a body of evidence.

Frame of Discernment: In Dempster-Shafer theory, the set of all hypotheses considered.

Dempster-Shafer Theory: General methodology, also known as the theory of belief functions, its rudiments are closely associated with uncertain reasoning.

Ignorance: In Dempster-Shafer theory, the level of mass value not discernible among the hypotheses.

Mass Value: In Dempster-Shafer theory, the level of exact belief in a focal element.

Non-Specificity: In Dempster-Shafer theory, the weighted average of the focal elements' mass values in a body of evidence, viewed as a species of a higher uncertainty type, encapsulated by the term ambiguity.

Plausibility: In Dempster-Shafer theory, the extent to which we fail to disbelieve a proposition lies in a focal element.

Dependency Parsing: Recent Advances

Ruket Çakıcı

ICCS School of Informatics, University of Edinburgh, UK

INTRODUCTION

Annotated data have recently become more important, and thus more abundant, in computational linguistics. They are used as training material for machine learning systems for a wide variety of applications from Parsing to Machine Translation (Quirk et al., 2005). Dependency representation is preferred for many languages because linguistic and semantic information is easier to retrieve from the more direct dependency representation. Dependencies are relations that are defined on words or smaller units where the sentences are divided into its elements called heads and their arguments, e.g. verbs and objects. Dependency parsing aims to predict these dependency relations between lexical units to retrieve information, mostly in the form of semantic interpretation or syntactic structure.

Parsing is usually considered as the first step of Natural Language Processing (NLP). To train statistical parsers, a sample of data annotated with necessary information is required. There are different views on how informative or functional representation of natural language sentences should be. There are different constraints on the design process such as: 1) how intuitive (natural) it is, 2) how easy to extract information from it is, and 3) how appropriately and unambiguously it represents the phenomena that occur in natural languages.

In this article, a review of statistical dependency parsing for different languages will be made and current challenges of designing dependency treebanks and dependency parsing will be discussed.

DEPENDENCY GRAMMAR

The concept of dependency grammar is usually attributed to Tesnière (1959) and Hays (1964). The dependency theory has since developed, especially with the works of Gross (1964), Gaiffman (1965), Robinson (1970), Mel'čuk (1988), Starosta (1988), Hudson (1984, 1990), Sgall et al. (1986), Barbero et al.

(1998), Duchier (2001), Menzel and Schröder (1998), Kruijff (2001).

Dependencies are defined as links between lexical entities (words or morphemes) that connect heads and their dependants. Dependencies may have labels, such as *subject*, *object*, and *determiner* or they can be unlabelled. A dependency tree is often defined as a directed, acyclic graph of links that are defined between words in a sentence. Dependencies are usually represented as trees where the root of the tree is a distinct node. Sometimes dependency links cross. Dependency graphs of this type are non-projective. Projectivity means that in surface structure a head and its dependants can only be separated by other dependants of the same head (and dependants of these dependants). Non-projective dependency trees cannot be translated to phrase structure trees unless treated specially. We can see in Table 1 that the notion of non-projectivity is very common across languages although distribution of it is usually rare in any given language. The fact that it is rare does not make it less important because it is this kind of phenomena that makes natural languages more interesting and that makes all the difference in the generative capacity of a grammar that is suggested to explain natural languages.

An example dependency tree is in Figure 1. The corresponding phrase structure tree is shown in Figure 2. The ROOT of this tree is "hit".

Given the basic concept of dependency, different theories of dependency grammar exist. Among many well known are: Functional Generative Description (Sgall et al., 1969, 1986), (Petkevič, 1987, 1995), Dependency Unification Grammar (DUG) Hellwig (1986, 2003), Meaning Text Theory (Gladkij and Mel'čuk, 1975), (Mel'čuk, 1988) and Lexibase (Starosta, 1988), Topological Dependency Grammar (Gerdes and Kahane, 2001). Kruijff (2001) also suggests a type of logic for dependency grammar, "Dependency Grammar Logic" which aims transparent semantic interpretation during parsing.

There are many open issues regarding the representation of dependency structure. Hays (1964)

Figure 1. Dependency Tree for the sentence “The red car hit the big motorcycle”

Figure 2. Phrase Structure Tree for the sentence in Figure 1

and Gaifman (1965) take dependency grammars as special cases of phrase structure grammars whereas Barbero et al. (1998), Menzel and Schröder (1998), Eisner (2000), Samuelsson (2000), Duchier (2001), Gerdes and Kahane (2001), Kruijff (2001) think they are completely different.

Generative capacity of dependency grammars has long been discussed (Gross, 1964), (Hays, 1964), (Gaifman, 1965), (Robinson, 1970). Dependency grammars were proved to be context-free (Gaifman, 1965). When natural languages were proved to be not context-free, but in a class called “Mildly Context-Sensitive” (Joshi, 1985) they were abandoned until 90s, when Vijayashanker and Weir (1994) showed that Head Grammars -an extension of CFGs- (Pollard, 1984) are mildly context-sensitive like Tree Adjoining Grammar (TAG), (Joshi et al., 1975) and Combinatory Categorical Grammar (CCG), (Steedman, 2000). Recently, Kuhlmann and Möhl (2007) defined “regular dependency languages” and showed that applying different combinations of gap-degree and well-nestedness restrictions on non-projectivity in these languages gave a class of mildly context-sensitive grammars.

DEPENDENCY TREEBANKS

Why Dependency Trees?

Many new corpora have been designed and created in the past few years. Dependency representation is preferred when these corpora are designed. This can be argued by the following properties of dependency trees:

1. They are easier to annotate than some other representation types like phrase structure trees (PST). There are fewer tags and labels (only as many as words in a sentence) and no internal nodes to name the phrases as in PSTs.
2. Some information such as predicate-argument structure can be extracted trivially from them which is not the case for PSTs.
3. Another interesting result is that some dependency parsers run much faster than PST parsers. Computational complexity of a standard PST parser is $O(n^5)$ whereas a non-projective DT parser runs in $O(n^2)$.

Dependency Treebanks

Table 1 compares dependency corpora of 19 languages¹. This information is gathered from CoNLL-X and CoNLL 2007 shared tasks on dependency parsing. The reader is referred to Buchholz and Marsi (2006) and Nivre et al. (2007) for more information on dependency treebanks included in the tasks. Although, the underlying theory is the same in all of these treebanks there are major differences in the outcome that originate from the questions like 1) how much information is needed to put in the dependency trees, 2) how strongly interlaced the different modules such as morphology syntax are in a language. For instance, Czech treebank (Böhmová et al., 2003) has 3 different levels of representation, namely,

morphological, grammatical and tecto-grammatical layers. Morphology-syntax interface in Turkish makes word-based dependencies inappropriate (Çakıcı, 2008). Therefore, dependencies are between morphological sub-groups called inflectional groups (IG) rather than words. These are two arguments among many on why it is very important to make a good feasibility study when designing a dependency treebank as different aspects of languages require different treatment.

DEPENDENCY PARSING

Statistical or data-driven parsing methods have gained more focus with the continuous introduction of new

*Table 1. Treebank information; #T = number of tokens * 1000, #S = number of sentences * 1000, #T/#S = tokens per sentence, %NST = % of non-scoring tokens (only in CoNLL-X), %NPR = % of non-projective relations, %NPS = % of non-projective sentences, IR = has informative root labels*

linguistic data. Parsing was more focused on training and parsing with phrase structure trees and specifically English language because the Penn Treebank (Marcus et al., 1993) was the only available source for a long time. With the introduction of treebanks of different languages it is now possible to explore the bounds of multilingual parsing.

The early efforts of data-driven dependency parsing were focused on translating dependency structures to phrase structure trees for which the parsers already existed. But it was realised quickly that doing this was not as trivial as previously thought. It is much more trivial and more intuitive to represent some phenomena with dependency trees rather than phrase structure trees such as local and global scrambling, in other words free word-order. Thus the incompatible translations of dependency structures to phrase structure trees resulted in varying degrees of loss of information.

Collins et al. (1999) reports results on Czech. He translates the dependency trees to phrase structure trees in the flattest way possible and names the internal nodes after part of speech tag of the head word of that node. He uses Model 2 in Collins (1999) and then evaluates the attachment score on the dependencies extracted from the resulting phrase structure trees of his parser. However, crossing dependencies cannot be translated into phrase structure trees (Çakıcı and Baldridge, 2006) unless surface order of the words is changed. But Collins et al. (1999) does not mention crossing dependencies, therefore, we do not know how he handled non-projectivity.

One of the earliest statistical systems that aims parsing dependency structures directly without an internal representation of translation is Eisner (1996). He proposes 3 different generative models. He evaluates them on the dependencies derived from the Wall Street Journal part of the Penn Treebank. Eisner reports 90 percent for probabilistic parsing of English samples from WSJ. He reports 93 percent attachment score when gold standard tags were used, which means 93 percent of all the dependencies are correct regardless of the percentage of the dependencies in each sentence. Eisner's parser is a projective parser thus it cannot inherently predict crossing dependencies.

Discriminative dependency parsers such as Kudo and Matsumoto (2000, 2002), and Yamada and Matsumoto (2003) were also developed. They use support vector machines to predict the next action of a deterministic

parser. Nivre et al. (2004) does this by memory-based learning. They are all deterministic parsers.

McDonald et al. (2005b) tried something new and applied graph spanning algorithms to dependency parsing. They formalise dependency parsing as the problem of finding a maximum spanning tree in a directed graph. MIRA is used to determine the weights of dependency links as part of this computation. This algorithm has two major advantages: it runs in $O(n^2)$ time and it can handle non-projective dependencies directly. They show that this algorithm significantly improves performance on dependency parsing for Czech, especially on sentences which contain at least one crossed dependency. Variations of this parser has been used in CoNLL-X shared task and received the highest ranking among the participants averaged over the results of all of the 13 languages (Buchholz and Marsi, 2006). However, when no linguistic or global constraints are applied it may yield absurd dependency sequences such as assigning two subjects to a verb (Riedel et al., 2006). McDonald (2005a) uses MIRA learning algorithm with Eisner's parser and reports results for projective parsing.

FUTURE TRENDS

There is growing body of work on creating new treebanks for different languages. Requirements for the design of these treebanks are at least as diverse as these natural languages themselves. For instance, some languages have a much more strong morphological component or freer word order than others. Understanding and modelling these in the form of annotated linguistic data will guide the understanding of natural language, and technological advancement will hopefully make it easier to understand the inner workings of the language faculty of humans. There are challenges both for dependency parsing and for the dependency theory. For instance, modelling long-distance dependencies and, multiple head dependencies are still awaiting attention and there is much to do on morphemic dependency approach where heads of phrases can be morphemes rather than words in a sentence for morphologically complex languages. Although these constitute a fraction of all the phenomena in natural languages, they are the "tricky" part of the NLP systems that will never be perfect as long as these natural phenomena are ignored.

CONCLUSION

This article has reviewed dependency grammar theory together with recent advances in statistical dependency parsing for different languages. Some current challenges in building dependency treebanks and dependency parsing have also been discussed. Dependency theory and practical applications of dependency representations have advantages and disadvantages. The fact that dependency parsing is easy to adapt to new languages, and is well-adapted to representing free word-order, makes it the preferred representation for many new linguistic corpora. Dependency parsing is also developing in the direction of multi-lingual parsing where a single system is required to be successful with different languages. This research may bring us closer to understanding the linguistic capacity of human brain, and thus to building better NLP systems.

KEY TERMS

Corpus (corpora plural): A collection of written or spoken material in machine-readable form.

Machine Translation (MT): The act of translating something by means of a machine, especially a computer.

Morpheme: The smallest unit of meaning. A word may consist of one morpheme (need), two morphemes (need/less, need/ing) or more (un/happi/ness).

Phrase Structure Tree: A structural representation of a sentence in the form of an inverted tree, with each node of the tree labelled according to the phrasal constituent it represents.

Rule-Based Parser: A parser that uses hand written (designed) rules as opposed to rules that are derived from the data.

Statistical Parser: A group of parsing methods within NLP. The methods have in common that they associate grammar rules with a probability.

Treebank: A text-corpus in which each sentence is annotated with syntactic structure. Syntactic structure is commonly represented as a tree structure. Treebanks can be used in corpus linguistics for studying syntactic phenomena or in computational linguistics for training or testing parsers.

ENDNOTE

Designing Unsupervised Hierarchical Fuzzy Logic Systems

M. Mohammadian

University of Canberra, Australia

INTRODUCTION

Systems such as robotic systems and systems with large input-output data tend to be difficult to model using mathematical techniques. These systems have typically high dimensionality and have degrees of uncertainty in many parameters. Artificial intelligence techniques such as neural networks, fuzzy logic, genetic algorithms and evolutionary algorithms have created new opportunities to solve complex systems. Application of fuzzy logic [Bai, Y., Zhuang H. and Wang, D. (2006)] in particular, to model and solve industrial problems is now wide spread and has universal acceptance. Fuzzy modelling or fuzzy identification has numerous practical applications in control, prediction and inference. It has been found useful when the system is either difficult to predict and or difficult to model by conventional methods. Fuzzy set theory provides a means for representing uncertainties. The underlying power of fuzzy logic is its ability to represent imprecise values in an understandable form. The majority of fuzzy logic systems to date have been static and based upon knowledge derived from imprecise heuristic knowledge of experienced operators, and where applicable also upon physical laws that governs the dynamics of the process.

Although its application to industrial problems has often produced results superior to classical control, the design procedures are limited by the heuristic rules of the system. It is simply assumed that the rules for the system are readily available or can be obtained. This implicit assumption limits the application of fuzzy logic to the cases of the system with a few parameters. The number of parameters of a system could be large. The number of fuzzy rules of a system is directly dependent on these parameters. As the number of parameters increase, the number of fuzzy rules of the system grows exponentially.

Genetic Algorithms can be used as a tool for the generation of fuzzy rules for a fuzzy logic system. This automatic generation of fuzzy rules, via genetic algo-

rithms, can be categorised into two learning techniques, supervised and unsupervised. In this paper unsupervised learning of fuzzy rules of hierarchical and multi-layer fuzzy logic control systems are considered. In unsupervised learning there is no external teacher or critic to oversee the learning process. In other words, there are no specific examples of the function to be learned by the system. Rather, provision is made for a task-independent measure of the quality or representation that the system is required to learn. That is the system learns statistical regularities of the input data and it develops the ability to learn the feature of the input data and thereby create new classes automatically [Mohammadian, M., Nainar, I. and Kingham, M. (1997)].

To perform unsupervised learning, a competitive learning strategy may be used. The individual strings of genetic algorithms compete with each other for the “opportunity” to respond to features contained in the input data. In its simplest form, the system operates in accordance with the strategy that ‘the fittest wins and survives’. That is the individual chromosome in a population with greatest fitness ‘wins’ the competition and gets selected for the genetic algorithms operations (cross-over and mutation). The other individuals in the population then have to compete with fit individual to survive.

The diversity of the learning tasks shown in this paper indicates genetic algorithm’s universality for concept learning in unsupervised manner. A hybrid integrated architecture incorporating fuzzy logic and genetic algorithm can generate fuzzy rules for problems requiring supervised or unsupervised learning. In this paper only unsupervised learning of fuzzy logic systems is considered. The learning of fuzzy rules and internal parameters in an unsupervised manner is performed using genetic algorithms. Simulations results have shown that the proposed system is capable of learning the control rules for hierarchical and multi-layer fuzzy logic systems. Application areas considered are, hierarchical control of a network of traffic light control and robotic systems.

A first step in the construction of a fuzzy logic system is to determine which variables are fundamentally important. Any number of these decision variables may appear, but the more that are used, the larger the rule set that must be found. It is known [Raju, S., Zhou J. and Kisner, R. A. (1990), Raju G. V. S. and Zhou, J. (1993), Kingham, M., Mohammadian, M., and Stonier, R. J. (1998)], that the total number of rules in a system is an exponential function of the number of system variables. In order to design a fuzzy system with the required accuracy, the number of rules increases exponentially with the number of input variables and its associated fuzzy sets for the fuzzy logic system. A way to avoid the explosion of fuzzy rule bases in fuzzy logic systems is to consider Hierarchical Fuzzy Logic Control (HFLC) [Raju G. V. S. and Zhou, J. (1993)]. A learning approach based on genetic algorithms [Goldberg, D. (1989)] is discussed in this paper for the determination of the rule bases of hierarchical fuzzy logic systems.

THE GENETIC FUZZY RULE GENERATOR ARCHITECTURE

In this section we show how to learn the fuzzy rules in a fuzzy logic rule base using a genetic algorithm. The full set of fuzzy rules is encoded as a single string in the genetic algorithm population. To facilitate this we develop the genetic fuzzy rule generator whose architecture consists of five basic steps

1. Divide the input and output spaces of the system to be controlled into fuzzy sets (regions),

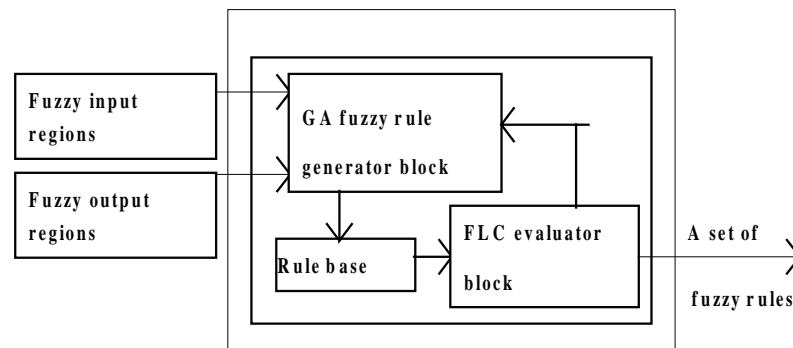

2. Encode the fuzzy rules into bit-string of 0 and 1,
3. Use a genetic algorithm as a learning procedure to generate set of fuzzy rules,
4. Use a fuzzy logic controller to assess the set of fuzzy rules and assign a value to each generated set of fuzzy rules,
5. Stop generating new sets of fuzzy rules once some performance criteria is met,

Figure 1 shows the genetic fuzzy rule generator architecture graphically. Suppose we wish to produce fuzzy rules for a fuzzy logic control with two inputs and single output. This simple two-input u_1, u_2 single-output y case is chosen in order to clarify the basic ideas of our new approach. Extensions to multi-output cases are straightforward. For more information on multi-output cases refer to Mohammadian et al [Mohammadian, M. and Stonier, R J., (1998)].

As a first step we divide the domain intervals of u_1, u_2 and y into different fuzzy sets. The number of the fuzzy sets is application dependent. Assume that we divide the interval for u_1, u_2 and y into 5, 7 and 7 fuzzy sets respectively. For each fuzzy set we assign a fuzzy membership function. Therefore a maximum of 35 fuzzy rules can be constructed for this system. Now the fuzzy rule base can be formed as a 5×7 table with cells to hold the corresponding actions that must be taken given the condition corresponding to u_1, u_2 are satisfied.

In step 2 we encode the input and output fuzzy sets into bit-strings (of 0 and 1). Each complete bit-string consists of 35 fuzzy rules for this example and each

Figure 1. Genetic fuzzy rule generator architecture

fuzzy rule base has the same input conditions but may have different output control signal assigned to it. Therefore we need only to encode the output signal of the fuzzy rule bit-strings into a complete bit-string. This will save the processing time for encoding and decoding of genetic algorithm's strings. In this case the length of an individual string has been reduced from 665 bits (i.e. 19×35) to 245 bits (i.e. 7×35). The choice of output control signal to be set for each fuzzy rule is made by the genetic algorithm. It initialises randomly a population of complete bit-strings. Each of these bit-strings is then decoded into fuzzy rules and evaluated by fuzzy logic controller to determine the fitness value for that bit-string. Application of proportional selection and mutation and one-point crossover operations can now proceed. Selection and crossover are the same as in simple genetic algorithms while the mutation operation is modified. Crossover and mutation take place based on the probability of crossover and mutation respectively. The mutation operator is changed to suit this problem, namely, an allele is selected at random and it is replaced by a random number ranging from 1

to 7 which represents in this example the five output fuzzy sets. The genetic algorithm process performs a self-directed search according to fitness value. In all applications in this paper we seek to minimise the fitness function. The process can be terminated after a desired number of generations or when the fitness value of the best string in a generation is less than some prescribed level.

VARIABLE SELECTION AND RULE BASE DECOMPOSITION

Traffic Light Control

Traffic light control is widely used to resolve conflicts among vehicle movements at intersections. The control system at each signalised intersection consists of the following three control elements, cycle time, phase splits and offset. Cycle time is the duration of completing all phases of a signal; phase split is the division of the cycle time into periods of green phase for competing approaches; and offset is the time difference in the starting times of the green phases of adjacent intersections.

In [Nainar, I., Mohammadian, M., Stonier, R. J. and Millar, J. (1996)] a fuzzy logic control scheme is proposed to overcome the lack of interactions between the neighbouring intersections. First, a traffic model is developed and a fuzzy control scheme for regulating the traffic flow approaching a single traffic intersection is proposed. A new fuzzy control scheme employing a supervisory fuzzy logic controller is then proposed to coordinate the three intersections based on the traffic conditions at all three intersections. Simulation results established the effectiveness of proposed scheme. Figure 2 shows the three intersections used in the simulation.

A supervisory fuzzy logic control system is then developed to coordinate the three intersections far more effectively than the three local fuzzy logic control systems. This is because using supervisory fuzzy logic controller each intersection is coordinated with all its neighbouring intersections [Nainar, I., Mohammadian, M., Stonier, R. J. and Millar, J. (1996)]. The fuzzy knowledge base of the supervisory fuzzy logic controller was learnt using genetic algorithms. The supervisory fuzzy logic controller developed to coordinate the three intersections coordinated the traffic

Figure 2. Three adjacent intersections

signals far more effectively than the three local fuzzy logic controllers. This is because using supervisory fuzzy logic controller each intersection is coordinated with all its neighbouring intersections. This proposed fuzzy logic control scheme can be effectively applied to on-line traffic control because of its ability to handle extensive traffic situations. Simulations results have shown that the multi-layer fuzzy logic system consisting of three local fuzzy logic controllers and the supervisory fuzzy logic controller is capable of reducing the waiting time on the network of the traffic intersections [Nainar, I., Mohammadian, M., Stonier, R. J. and Millar, J. (1996)].

Collision-Avoidance in a Robot System

Consider the following collision-avoidance problem in a simulated, point mass, two robot system. A three-level hierarchical, fuzzy logic system was proposed to solve the problem, full details can be found in [Mohammadian, M. and Stonier, R. J. (1998)], see also [Mohammadian, M. and Stonier, R. J. (1995)]. In the first layer, two knowledge bases, one for each robot, are developed to find the steering angle to control each robot to its target. In the second layer two new knowledge bases are developed using the knowledge in the first layer to control the speed of each robot so that each robot approaches its target with near zero speed. Finally in the third layer, a single knowledge base is developed to modify the controls of each robot to avoid collision in a restricted common workspace, see Figure 3.

In Figure 3, x, y gives the physical position of the robot on the plane, ϕ is the directional heading of the robot, q is the steering angle, D_1 and D_2 are the distances of the two robots from their respective targets, S_1 and S_2 are the speeds of the two robots, D is the distance between the two robots and $q_1, q_2, q_1', q_2', s_1'$ and s_2' are the updates of variable outputs for the last two layers. An important issue in this example is that of learning knowledge in a given layer sufficient for use in higher layers. In the first layer of the hierarchical fuzzy logic system, ignoring the possibility of collision, steering angles for the control of each robot to their associated target were determined by genetic algorithms. In the second layer genetic algorithm was used to determine adjustments to steering angle and speed of each robot to control the speed of the robot when arriving to its target. Next another layer is developed to adjust the speed and steering angle of the robots to avoid collision of the robots. Consider the knowledge base of a single robot in layer one. It is not sufficient to learn a fuzzy knowledge base from an initial configuration and use this knowledge base for information on the steering angle of the robot to learn fuzzy controllers in the second layer. Quite clearly this knowledge base is only guaranteed to be effective from this initial configuration as not all the fuzzy rules will have fired in taking the robot to its target. We have to find a knowledge base that is effective to some acceptable measure, in controlling the robot to its target from 'any' initial configuration. One way is to first learn a set of local fuzzy controllers, each knowledge base learnt by an

Figure 3. Hierarchical structure for collision-avoidance

genetic algorithms from a given initial configuration within a set of initial configurations spread uniformly over the configuration space. These knowledge bases can then be *fused* through a *fuzzy amalgamation* process [Stonier, R. J. and Mohammadian, M. (1995)] into the global (final), fuzzy control knowledge base. An alternative approach [Mohammadian, M. and Stonier, R. J. (1996), Stonier, R. J. and Mohammadian, M. (1998)], is to develop an genetic algorithms to learn directly the ‘final’ knowledge base by itself over the region of initial configurations.

In conclusion the proposed hierarchical fuzzy logic system is capable of controlling the multi-robot system successfully. By using hierarchical fuzzy logic system the number of control laws is reduced. In the first layer of hierarchical fuzzy logic system ignoring the possibility of collision, steering angles for the control of each robot to their associated target were determined by genetic algorithms. In the second layer genetic algorithm was used to determine adjustments to steering angle and speed of each robot to control the speed of the robot when arriving to its target. Next another layer is developed to adjust the speed and steering angle of the robots to avoid collision of the robots. If only one fuzzy logic system was used to solve this problem with the inputs x , y , ϕ of each robot and D each with the same fuzzy sets described in this paper then there would be 153125 fuzzy rule needed for its fuzzy knowledge base. Using a hierarchical fuzzy logic system there is a total number of 1645 fuzzy rules for this system. The hierarchical concept learning using the proposed method makes easier the development of fuzzy logic control systems, by encouraging the development of fuzzy logic controllers where the large number of systems parameters inhibits the construction of such controllers. For more details, we refer the reader to the cited papers.

ISSUES IN RULE BASE IDENTIFICATION

Research into this area has been described as genetic fuzzy systems using the classical genetic algorithm has been surveyed by Cordon [Cordon, O., Herrera, F. and Zwir, I. (2002)], see also [Cordon, O., Herrera, F., Hoffmann, F. and Magdalena, L. (2001)]. Genetic algorithms is employed to learn or tune different components of a fuzzy logic system such as the fuzzy

knowledge base and the membership functions in the inference process. This is usually accomplished by using a genetic algorithms to produce the “best” fuzzy rules and membership functions/parameters with respect to an optimisation criterion. There are three main approaches in the literature for learning the rules in a fuzzy knowledge base. They are, the Pittsburgh approach, the Michigan approach and the iterative rule-learning approach [Cordon, O., Herrera, F., Hoffmann, F. and Magdalena, L. (2001)]. The Pittsburgh and Michigan approaches are the most commonly used methods in the area.

Research by the authors, colleagues and postgraduate students has predominately used the Pittsburgh approach with success in learning the fuzzy rules in complex systems, across hierarchical and multi-layered structures in problems [Stonier, R. J. and Zajackowski, J. (2003), Kingham, M., Mohammadian, M. and Stonier, R. J. (1998), Mohammadian, M. and Kingham, M. (2004), Mohammadian, M. (2002), Nainar, I., Mohammadian, M., Stonier, R. J. and Millar, J. (1996), Mohammadian, M. and Stonier, R. J. (1998), Stonier, R. J. and Mohammadian, M. (1995), Thomas, P. J. and Stonier, R. J. (2003), Thomas, P. J. and Stonier, R. J. (2003a)].

FUTURE TRENDS

In using the Pittsburgh approach the coding of the fuzzy rule base as a linear string in an evolutionary algorithm has its drawbacks other than the string may even be relatively large in length under decomposition into multi-layer and hierarchical structures. One is that this is a specific linear encoding of a nonlinear structure and typical one-point crossover when implemented introduces bias when reversing the coding to obtain the fuzzy logic rule base. Using co-evolutionary algorithms is also another option that needs further investigation.

CONCLUSION

This paper described the issues in the construction of a hierarchical fuzzy logic system to model a complex (nonlinear) system. The learning of fuzzy rules in such systems using genetic algorithms was proposed and it was shown to be feasible. Whilst the decomposition

into hierarchical/multi-layered fuzzy logic sub-systems reduces greatly the number of fuzzy rules to be defined and to be learnt, other issues arise such as the decomposition is not unique and that it may give rise to variables with no physical significance. This can raise then major difficulties in obtaining a complete class of rules from experts even when the number of variables is small.

ACKNOWLEDGMENT

The authors wish to thank those colleagues and students who have helped in this research and associated publications.

KEY TERMS

Fusing Variables: Fusing variables is a method for reducing the number of rules in a fuzzy rule base. The variables are fused (combined) together before input into the inference engine, thereby reducing the number of rules in the knowledge base.

Fuzzy Logic: Fuzzy sets and Fuzzy Logic were introduced in 1965 by Lotfi Zadeh as a new way to represent vagueness in applications. They are a generalisation of sets in conventional set theory. Fuzzy Logic (FL) aims at modelling imprecise models of reasoning, such as common sense reasoning for uncertain complex processes. A system for representing the meaning of lexically imprecise proposition in natural language structure through the proposition being represented as fuzzy constraints on a variable is provided. Fuzzy logic controllers have been applied to many nonlinear control systems successfully. Linguistic rather than crisp numerical rules are used to control the processes.

Fuzzy Rule Base (Fuzzy If-Then rules): Fuzzy If-Then or fuzzy conditional statements are expressions of the form “If **A** Then **B**”, where **A** and **B** are labels of fuzzy sets characterised by appropriate membership functions. Due to their concise form, fuzzy If-Then rules are often employed to capture the imprecise modes of reasoning that play an essential role in the human ability to make decision in an environment of uncertainty and imprecision. The set of If-Then rules relate to a fuzzy logic system that are stored together is called a Fuzzy Rule Base.

Genetic Algorithms: Genetic Algorithms (GAs) are algorithms that use operations found in natural genetics to guide their way through a search space and are increasingly being used in the field of optimisation. The robust nature and simple mechanics of genetic algorithms make them inviting tools for search, learning and optimization. Genetic algorithms are based on computational models of fundamental evolutionary processes such as selection, recombination and mutation.

Genetic Algorithms Components: In its simplest form, a genetic algorithm has the following components:

1. *Fitness* - A positive measure of utility, called fitness, is determined for individuals in a population. This fitness value is a quantitative measure of how well a given individual compares to others in the population.
2. *Selection* - Population individuals are assigned a number of copies in a mating pool that is used to construct a new population. The higher a population individual's fitness, the more copies in the mating pool it receives.
3. *Recombination* - Individuals from the mating pool are recombined to form new individuals, called children. A common recombination method is one-point crossover.
4. *Mutation* - Each individual is mutated with some small probability $\ll 1.0$. Mutation is a mechanism for maintaining diversity in the population.

Hierarchical Fuzzy Logic Systems: The idea of hierarchical fuzzy logic control systems is to put the input variables into a collection of low-dimensional fuzzy logic control systems, instead of creating a single high dimensional rule base for a fuzzy logic control system. Each low-dimensional fuzzy logic control system constitutes a level in the hierarchical fuzzy logic control system. Hierarchical fuzzy logic control is one approach to avoid rule explosion problem. It has the property that the number of rules needed to construct the fuzzy system increases only linearly with the number of variables in the system

Unsupervised Learning: In unsupervised learning there is no external teacher or critic to oversee the learning process. In other words, there are no specific examples of the function to be learned by the system. Rather, provision is made for a task-independent measure of the quality or representation that the system is required to learn. That is the system learns statistical regularities of the input data and it develops the ability to learn the feature of the input data and thereby create new classes automatically.

Developmental Robotics

INTRODUCTION

Human intelligence is acquired through a prolonged period of maturation and growth during which a single fertilized egg first turns into an embryo, then grows into a newborn baby, and eventually becomes an adult individual—which, typically before growing old and dying, reproduces. The developmental process is inherently robust and flexible, and biological organisms show an amazing ability during their development to devise adaptive strategies and solutions to cope with environmental changes and guarantee their survival. Because evolution has selected development as the process through which to realize some of the highest known forms of intelligence, it is plausible to assume that development is mechanistically crucial to emulate such intelligence in human-made artifacts.

BACKGROUND

The idea that development might be a good avenue to understand and construct cognition is not new. Already Turing (1950) suggested that using some kind of developmental approach might be a good strategy. In the context of robotics, many of the original ideas can be traced back to embodied artificial intelligence (embodied AI), a movement started by Rodney Brooks at the beginning of the 1980s (Brooks et al., 1998), and the notion of enaction (Varela et al., 1991) according to which cognitive structures emerge from recurrent sensorimotor patterns that enable action to be perceptually guided. Researchers of embodied AI believe that intelligence can only come from the reciprocal interaction across multiple time scales between brain and body of an agent, and its environment. In a sense, throughout life, experience is learned and common sense is acquired, which then supports more complex reasoning. This general bootstrapping of

intelligence has been called “cognitive incrementalism” (Clark, 2001).

DEVELOPMENTAL ROBOTICS

Developmental robotics (also known as epigenetic or ontogenetic robotics) is a highly interdisciplinary subfield of robotics in which ideas from artificial intelligence, developmental psychology, neuroscience, and dynamical systems theory play a pivotal role in motivating the research (Asada *et al.*, 2001; Lungarella *et al.*, 2003; Weng *et al.*, 2001; Zlatev & Balkenius, 2001). Developmental robotics aims to model the development of increasingly complex cognitive processes in natural and artificial systems and to understand how such processes emerge through physical and social interaction. The idea is to realize artificial cognitive systems not by simply programming them to solve a specific task, but rather by initiating and maintaining a developmental process during which the systems interact with their physical environments (i.e. through their bodies or tools), as well as with their social environments (i.e. with people or other robots). Cognition, after all, is the result of a process of self-organization (spontaneous emergence of order) and co-development between a developing organism and its surrounding environment. Although some researchers use simulated environments and computational models (e.g. Mareschal et al., 2007), often robots are employed as testing platforms for theoretical models of the development of cognitive abilities – the rationale being that if a model is instantiated in a system interacting with the real world, a great deal can be learned about its strengths and potential flaws (Fig. 1). Unlike evolutionary robotics which operates on phylogenetic time scales and populations of many individuals, developmental robotics capitalizes on

Figure 1. Developmental robots. (a) iCub (<http://www.robotcub.org>) (b) Babybot (<http://www.liralab.it/babybot/robot.htm>) (c) Infanoid (<http://univ.nict.go.jp/people/xkozima/infanoid/robot-eng.html#infanoid>).

“short” (ontogenetic) time scales and single individuals (or small groups of individuals).

AREAS OF INTEREST

The spectrum of developmental robotics research can be roughly segmented into four primary areas of interest. Although instances may exist that fall into multiple categories, the suggested grouping should provide at least some order in the large spectrum of issues addressed by developmental roboticists.

Socially oriented interaction: This category includes research on robots that communicate or learn particular skills via social interaction with humans or other robots. Examples are imitation learning, communication and language acquisition, attention sharing, turn-taking behavior, and social regulation (Dautenhahn, 2007; Steels, 2006).

Non-social interaction: Studies on robots characterized by a direct and strong coupling between sensorimotor processes and the local environment (e.g. inanimate objects), but which do not interact

with other robots or humans. Examples are visually-guided grasping and manipulation, tool-use, perceptual categorization, and navigation (Fitzpatrick *et al.*, 2007; Nabeshima *et al.*, 2006).

Agent-centered sensorimotor control: In these studies, robots are used to investigate the exploration of bodily capabilities, the effect of morphological changes on motor skill acquisition, as well as self-supervised learning schemes not linked to any functional goal. Examples include self-exploration, categorization of motor patterns, motor babbling, and learning to walk or crawl (Demiris & Meltzoff, 2007; Lungarella, 2004).

Mechanisms and principles: This category embraces research on principles, mechanisms or processes thought to increase the adaptivity of a behaving system. Examples are: developmental and neural plasticity, mirror neurons, motivation, freezing and freeing of degrees of freedom, and synergies; characterization of complexity and emergence, study of the effects of adaptation and growth, and practical work on body construction or development (Arbib *et al.*, 2007; Oudeyer *et al.*, 2007; Lungarella & Sporns, 2006).

PRINCIPLES FOR DEVELOPMENTAL SYSTEMS

By contrast to traditional disciplines such as physics or mathematics, which are described by well-known basic principles, the fundamental principles governing the dynamics of developmental systems are unknown. Could there be laws governing developmental systems or a theory? Although various attempts have been initiated (Asada *et al.*, 2001; Brooks *et al.*, 1998; Weng *et al.*, 2001), it is fair to say that to date no such theory has emerged. Here, *en route* to such a theory, we point out a set of candidate principles. An approach based on principles is preferable for constructing intelligent autonomous systems, because it allows capturing design ideas and heuristics in a concise and pertinent way, avoiding blind trial-and-error. Principles can be abstracted from biological systems, and their inspiration can take place at several levels, ranging from a “faithful” replication of biological mechanisms to a rather generic implementation of biological principles leaving room for dynamics intrinsic to artifacts but not found in natural systems. In what follows we summarize five key principles revealed by observations of human development which may be used to construct developmental robots.

The Value Principle

Observations: Value systems are neural structures that mediate value and saliency and are found in virtually all vertebrate species. They are necessary for an organism’s behavioral adaptation to salient (meaningful) environmental cues. By linking behavior and neuroplasticity, value systems are essential for deciding what to do in a particular situation (Sporns, 2007).

Lessons for robotics: The action of value systems – through adaptive changes in sensorimotor connections and inputs – enables an embodied agent to learn action strategies without external supervision by increasing the likelihood that a “good” movement pattern can recur in the same behavioral context. Value systems may also be used to guide an exploratory process and hence allow a system to learn sensorimotor patterns more efficiently compared to a pure random or a systematic exploration (Gómez & Eggenberger, 2007). By imposing constraints through value-dependent modulation of saliency, the

search space can be considerably reduced. Examples of value systems in the brain include the dopaminergic, cholinergic, and noradrenergic systems; based on them, several models have been implemented and embedded in developmental robots (Sporns, 2007).

The Principle of Information Self-Structuring

Observations: Infants frequently engage in repetitive (seemingly dull) behavioral patterns: they look at objects, grasp them, stick them into their mouths, bang them on the floor, and so on. It is through such interactions that intelligence in humans develops as children grow up interacting with their environment (Smith & Breazeal, 2007; Smith & Gasser, 2005).

Lessons for robotics: The first important lesson is that information processing (neural coding) needs to be considered in the context of the embeddedness of the organism within its eco-niche. That is, robots and organisms are exposed to a barrage of sensory data shaped by sensorimotor interactions and morphology (Lungarella & Sporns, 2006). Information is not passively absorbed from the surrounding environment but is selected and shaped by actions on the environment. Second, information structure does not exist before the interaction occurs, but emerges only while the interaction is taking place. The absence of interaction would lead to a large amount of unstructured data and consequently to stronger requirements on neural coding, and – in the worst case – to the inability to learn. It follows that embodied interaction lies at the root of a powerful learning mechanism as it enables the creation of time-locked correlations and the discovery of higher-order regularities that transcend the individual sensory modalities. [Lungarella (2004; “principle of information self-structuring”)].

The Principle of Incremental Complexity

Observations: Infants’ early experiences are strongly constrained by the immaturity of their sensory, motor, and neural systems. Such early constraints, which at first appear to be an inadequacy, are in fact of advantage, because they effectively decrease the “information overload” that otherwise would overwhelm the infant (Bjorklund & Green, 1992).

Lessons for robotics: In order for an organism – natural or artificial – to learn to control its own

complex brain-body system, it might be a good strategy to start simple and gradually build on top of acquired abilities. The well-timed and gradual co-development of body morphology and neural system provides an incremental approach to deal with a complex and unpredictable world. Early “morphological constraints” and “cognitive limitations” can lead to more adaptive systems as they allow exploiting the role that experience plays in shaping the “cognitive” architecture. If an organism was to begin by using its full complexity, it would never be able to learn anything (Gómez *et al.*, 2004). It follows that designers should not try to “code” a full-fledged ready-to-be-used intelligence module directly into an artificial system. Instead, the system should be able to discover on its own the most effective ways of assembling low-level components into novel solutions [Lungarella (2004; “starting simple”); Pfeifer & Bongard (2007; “incremental process principle”)].

The Principle of Interactive Emergence

Observations: Development is not determined by innate mechanisms alone (in other words: not everything should be pre-programmed). Cognitive structure, for instance, is largely dependent on the interaction history of the developing system with the environment in which it is embedded (Hendriks-Jansen, 1996).

Lessons for robotics: In traditional engineering the designer of the system imposes (“hard-wires”) the structure of the controller and the controlled system. Designers of adaptive robots, however, should avoid implementing the robot’s control structure according to their understanding of the robot’s physics, but should endow the robot with means to acquire its own understanding through self-exploration and interaction with the environment. Systems designed for emergence tend to be more adaptive with respect to uncertainties and perturbations. The ability to maintain performance in the face of changes (such as growth or task modifications) is a long-recognized property of living systems. Such robustness is achieved through a host of mechanisms: feedback, modularity, redundancy, structural stability, and plasticity [Dautenhahn (2007; “interactive emergence”); Hendriks-Jansen (1996; “interactive emergence”); Prince *et al.* (2005; “ongoing emergence”)].

The Principle of Cognitive Scaffolding

Observations: Development takes place among conspecifics with similar internal systems and similar external bodies (Smith & Breazeal, 2007). Human infants, for instance, are endowed from an early age with the means to engage in simple, but nevertheless crucial social interactions, e.g. they show preferences for human faces, smell, and speech, and they imitate protruding tongues, smiles, and other facial expressions (Demiris & Meltzoff, 2007).

Lessons for robotics: Social interaction bears many potential advantages for developmental robots: (a) it increases the system’s behavioral diversity through mimicry and imitation (Demiris & Meltzoff, 2007); (b) it supports the emergence of language and communication, and symbol grounding (Steels, 2006); and (c) it helps structure the robot’s environment by simplifying and speeding up the learning of tasks and the acquisition of skills. Scaffolding is often employed by parents and caretakers (intentionally or not) to support, shape, and guide the development of infants. Similarly, the social world of the robot should be prepared to teach the robot progressively novel and more complex tasks without overwhelming its artificial cognitive structure [Lungarella (2004; “social interaction principle”); Mareschal *et al.* (2007; “ensocialment”); Smith & Breazeal (2007; “coupling to intelligent others”)].

FUTURE TRENDS

The further success of developmental robotics will depend on the extent to which theorists and experimentalists will be able to identify universal principles spanning the multiple levels at which developmental systems operate. Here, we briefly indicate some “hot” issues that need to be tackled *en route* to a theory of developmental systems.

Semiotics: It is necessary to address the issue of how developmental robots (and embodied agents in general) can attribute meaning to symbols and construct semiotic systems. A promising approach, explored under the label of “semiotic dynamics”, is that such semiotic systems and the associated information structure are continuously invented and negotiated by groups of people or agents, and are used for communication and information organization (Steels, 2006).

Core knowledge: An organism cannot develop without some built-in ability. If all abilities are built in, however, the organism does not develop either. It will therefore be important to understand with what sort of core knowledge and explorative behaviors a developmental system has to be endowed, so that it can autonomously develop novel skills. One of the greatest challenges will be to identify core abilities and how they interact during development in building basic skills (Spelke, 2000).

Core motives: It is necessary to conduct research on general capacities such as creativity, curiosity, motivations, action selection, and prediction (i.e. the ability to foresee consequence of actions). Ideally, no tasks should be pre-specified to the robot, which should only be provided with an internal abstract reward function and a set of basic motivational (or emotional) drives that could push it to continuously master new know-how and skills (Lewis, 2000; Oudeyer et al., 2007).

Self-exploration: Another important challenge is the one of self-exploration or self-programming (Bongard et al., 2006). Control theory assumes that target values and states are initially provided by the system's designer, whereas in biology, such targets are created and revised continuously by the system itself. Such spontaneous "self-determined evolution" or "autonomous development" is beyond the scope of current control theory and needs to be addressed in future research.

Learning causality: In a natural setting, no teacher can possibly provide a detailed learning signal and sufficient training data. Mechanisms will have to be created to characterize learning in an "ecological context" and for the developing agent to collect relevant learning material on its own. One significant future avenue will be to endow systems with the possibility to recognize progressively longer chains of cause and effect (Chater et al., 2006).

Growth: As mentioned in the introduction, intelligence is acquired through a process of self-assembly, growth, and maturation. It will be important to study how physical growth, change of shape and body composition, as well as material properties of sensors and actuators affect and guide the emergence of cognition. This will allow connecting developmental robotics to computational developmental biology (Gómez & Eggenberger, 2007; Kumar & Bentley, 2003).

CONCLUSION

The study of intelligent systems raises many fundamental, but also very difficult questions. Can machines think or feel? Can they autonomously acquire novel skills? Can the interaction of the body, brain, and environment be exploited to discover novel and creative solutions to problems? Developmental robotics may be an approach to explore such long standing issues. At this point, the field is bubbling with activity. Its popularity is partly due to recent technological advances which have allowed the design of robots whose "kinematic complexity" is comparable to that of humans (Fig. 1). The success of developmental robotics will ultimately depend on whether it will be possible to crystallize its central assumptions into a theory. While much additional work is surely needed to arrive at or even approach a general theory of intelligence, the beginnings of a new synthesis are on the horizon. Perhaps, finally, we will come closer to understanding and building (growing) human-like intelligence. Exciting times are ahead of us.

KEY TERMS

Adaptation: Refers to particular adjustments that organisms undergo to cope with environmental and morphological changes. In biology one can distinguish four types of adaptation: evolutionary, physiological, sensory, and learning.

Bootstrapping: Designates the process of starting with a minimal set of functions and building increasingly more functionality in a step by step manner on top of structures already present in the system.

Degrees of freedom problem: The problem of learning how to control a system with a very large number of degrees of freedom (also known as Bernstein's problem).

Embodiment: Refers to the fact that intelligence requires a body, and cannot merely exist in the form of an abstract algorithm.

Emergence: A process where phenomena at a certain level arise from interactions at lower levels. The term is sometimes used to denote a property of a system not contained in any one of its parts.

Scaffolding: Encompasses all kinds of external support and aids that simplify the learning of tasks and the acquisition of new skills.

Semiotic Dynamics: Field that studies how meaningful symbolic structures originate, spread, and evolve over time within populations, by combining linguistics and cognitive science with theoretical tools from complex systems and computer science.

Device-Level Majority von Neumann Multiplexing

INTRODUCTION

This chapter starts from an exact gate-level reliability analysis of von Neumann multiplexing using majority gates of increasing fan-ins ($\Delta = 3, 5, 7, 9, 11$) at the smallest redundancy factors ($R_F = 2\Delta$), and details an accurate device-level analysis. The analysis complements well-known theoretical and simulation results. The gate-level analysis is exact as obtained using exhaustive counting. The extension (of the exact gate-level analysis) to device-level errors will allow us to analyze von Neumann majority multiplexing with respect to device malfunctions. These results explain abnormal behaviors of von Neumann multiplexing reported based on Monte Carlo simulations. These analyses show that *device-level reliability results are quite different from the gate-level ones, and could have profound implications for future (nano)circuit designs.*

SIA (2005) predicts that the semiconductor industry will continue its success in scaling CMOS for a few more generations. This scaling should become very difficult when approaching 16 nm. Scaling might continue further, but alternative nanodevices might be integrated with CMOS on the same platform. Besides the higher sensitivities of future ultra-small devices, the simultaneous increase of their numbers will create the ripe conditions for an inflection point in the way we deal with reliability.

With geometries shrinking the *available reliability margins* of the future nano(devices) are considerably being reduced (Constantinescu, 2003), (Beiu et al., 2004). From the chip designers' perspective, reliability currently manifests itself as time-dependent uncertainties and variations of electrical parameters. In the nano-era, these *device-level parametric uncertainties*

are becoming too high to handle with prevailing worst-case design techniques—without incurring significant penalty in terms of area, delay, and power/energy. The global picture is that reliability looks like one of the greatest threats to the design of future ICs. For emerging nanodevices and their associated interconnects the anticipated probabilities of failures, could make future nano-ICs prohibitively unreliable. The present design approach based on the conventional zero-defect foundation is seriously being challenged. Therefore, fault- and defect-tolerance techniques will have to be considered from the early design phases.

Reliability for beyond CMOS technologies (Hutchby et al., 2002) (Waser, 2005) is expected to get even worse, as device failure rates are predicted to be as high as 10% for single electron technology, or SET (Likharev, 1999), going up to 30% for self-assembled DNA (Feldkamp & Niemeyer, 2006) (Lin et al., 2006). Additionally, a comprehensive analysis of carbon nano tubes for future interconnects (Massoud & Nieuwoudt, 2006) estimated the variations in delay at about 60% from the nominal value. Recently, defect rates of 60% were reported for a 160 Kbit molecular electronic memory (Green et al., 2007). Achieving 100% correctness with 10^{12} nanodevices will be not only outrageously expensive, but plainly impossible! Relaxing the requirement of 100% correctness should reduce *manufacturing, verification, and test* costs, while leading to more transient and permanent errors. It follows that most (if not all) of these errors will have to be compensated by architectural techniques (Nikolić et al., 2001) (Constantinescu, 2003) (Beiu et al., 2004) (Beiu & Rückert, 2009).

From the system design perspective errors fall into: *permanent* (defects), *intermittent*, and *transient*

(faults). The origins of these errors can be found in the manufacturing process, the physical changes appearing during operation, as well as sensitivity to internal and external noises and variations. It is not clear if emerging nanotechnologies will not require new fault models, or if multiple errors might have to be dealt with. Kuo (2006) even mentioned that: “*we are unsure as to whether much of the knowledge that is based on past technologies is still valid for reliability analysis.*” The well-known approach for fighting against errors is to incorporate redundancy: either *static* (in space, time, or information) or *dynamic* (requiring fault detection, location, containment, and recovery). Space (hardware) redundancy relies on voters (generic, inexact, mid-value, median, weighted average, analog, hybrid, etc.) and includes: modular redundancy, cascaded modular redundancy, and multiplexing like von Neumann multiplexing vN-MUX (von Neumann, 1952), enhanced vN-MUX (Roy & Beiu, 2004), and parallel restitution (Sadek et al., 2004). Time redundancy is trading space for time, while information redundancy is based on error detection and error correction codes.

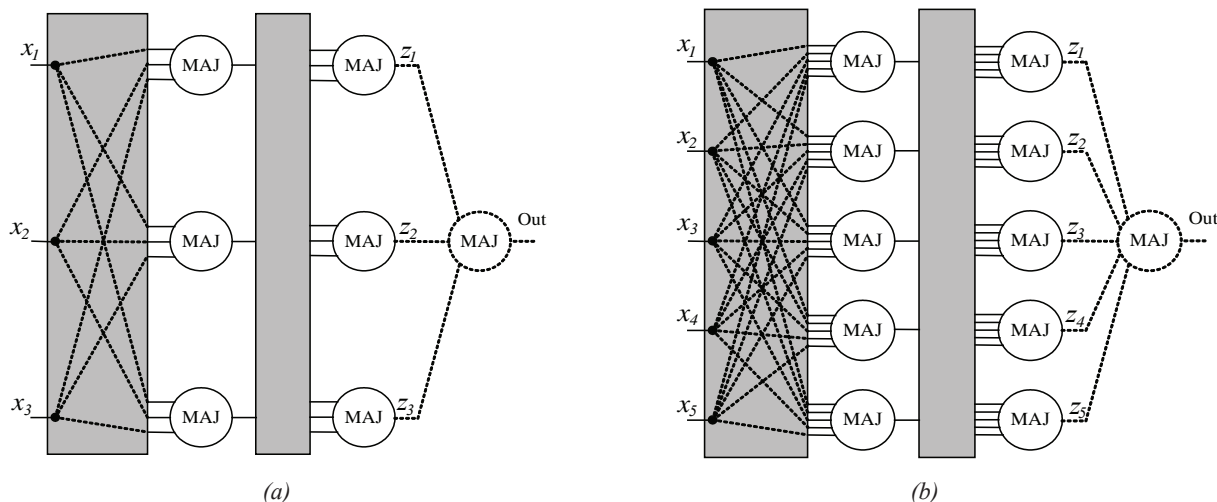

This chapter explores the performance of vN-MUX when using majority gates of *fan-in* Δ (MAJ- Δ). The aim is to get a clear understanding of the trade-offs between the reliability enhancements obtained when using MAJ- Δ vN-MUX at the smallest redundancy factors $R_F = 2\Delta$ (see Fig. 1) on one side, versus both the fan-ins and the unreliable nanodevices on the other side. We shall start by reviewing some theoretical and simulation results for vN-MUX in Background section.

Exact gate-level simulations (as based on an exhaustive counting algorithm) and accurate device-level estimates, including details of the effects played by nanodevices on MAJ- Δ vN-MUX, are introduced in the Main Focus of the Chapter section. Finally, implications and future trends are discussed in Future Trends, and conclusions and further directions of research are ending this chapter.

BACKGROUND

Multiplexing was introduced by von Neumann as a scheme for reliable computations (von Neumann, 1952). vN-MUX is based on successive computing stages alternating with random interconnection stages. Each computing stage contains a set of redundant gates. Although vN-MUX was originally exemplified for NAND-2 it can be implemented using any type of gate, and could be applied to any level of abstraction (subcircuits, gates, or devices). The ‘multiplexing’ of each computation tries to reduce the likelihood of errors propagating further, by selecting the more-likely result(s) at each stage. Redundancy is quantified by a redundancy factor R_F , which indicates the multiplicative increase in the number of gates (subcircuits, or devices). In his original study, von Neumann (1952) assumed independent (un-correlated) gate failures pf_{GATE} and very large R_F . The performance of NAND-2 vN-MUX was compared with other fault-tolerant techniques in (Forshaw et al., 2001), and it was analyzed at lower

Figure 1. Minimum redundancy MAJ- Δ vN-MUX: (a) MAJ-3 ($R_F = 6$); and (b) MAJ-5 ($R_F = 10$)

R_F (30 to 3,000) in (Han & Jonker, 2002), while the first exact analysis at very low R_F (3 to 100) for MAJ-3 vN-MUX was done in (Roy & Beiu, 2004).

The issue of which gate should one use is debatable (Ibrahim & Beiu, 2007). It was proven that using MAJ-3 could lead to improved vN-MUX computations only for $pf_{MAJ-3} < 0.0197$ (von Neumann, 1952), (Roy & Beiu, 2004). This outperforms the NAND-2 error threshold $pf_{NAND-2} < 0.0107$ (von Neumann, 1952), (Sadek et al., 2004). Several other studies have shown that the error thresholds of MAJ are higher than those of NAND when used in vN-MUX. Evans (1994) proved that:

$$pf_{MAJ-\Delta} \leq \frac{1}{2} - \frac{2^{\Delta-2}}{\Delta \times C_{\Delta-1}^{(\Delta-1)/2}}, \quad (1)$$

while the error threshold for NAND- Δ was determined in (Gao et al., 2005) by solving:

$$\left(1 + \frac{1}{\Delta}\right) \times \left[\frac{1}{\Delta(1 - 2pf_{NAND-\Delta})} \right]^{1/(\Delta-1)} = 1 - pf_{NAND-\Delta}. \quad (2)$$

An approach for getting a better understanding of vN-MUX at very small R_F is to use Monte Carlo simulations (Beiu, 2005), (Beiu & Sulieman, 2006), (Beiu et al., 2006). These have revealed that the reliability of NAND-2 vN-MUX is in fact better than that of MAJ-3 vN-MUX (at $R_F = 6$) for small geometrical variations v . As opposed to the theoretical results—where the reliability of MAJ-3 vN-MUX is *always* better than NAND-2 vN-MUX—the Monte Carlo simulations showed that MAJ-3 vN-MUX is better than NAND-2 vN-MUX, but only for $v > 3.4\%$. Such results were neither predicted (by theory) nor suggested by (gate-level) simulations.

It is to be highlighted here that all the theoretical publications discuss unreliable *organs*, *gates*, *nodes*, *circuits*, or *formulas*, but very few mention devices. For getting a clear picture we have started by developing an exhaustive counting algorithm which exactly calculates the reliability of MAJ- Δ vN-MUX (Beiu et al., 2007). The probability of failure of MAJ- Δ vN-MUX is:

$$Pf_{MAJ-\Delta \text{ vN-MUX}} = \sum_{k=0}^{2\Delta} \left[\sum_{i=1}^{C_{2\Delta}^k} \frac{(\#vNfaults)_{ik} \cdot pf_{MAJ-\Delta}^k \cdot (1 - pf_{MAJ-\Delta})^{2\Delta-k}}{2^\Delta} \right]. \quad (3)$$

The results based on exhaustive counting when varying $pf_{MAJ-\Delta}$ have confirmed both the theoretical and the simulation ones. MAJ- Δ vN-MUX at the minimum redundancy factor $R_F = 2\Delta$ improves the reliability over MAJ- Δ when $pf_{MAJ-\Delta} \leq 10\%$, and increasing Δ increases the reliability. When $pf_{MAJ-\Delta} > 10\%$, using vN-MUX increases the reliability over that of MAJ- Δ as long as $pf_{MAJ-\Delta}$ is lower than a certain error threshold. If $pf_{MAJ-\Delta}$ is above the error threshold, the use of vN-MUX is detrimental, as the reliability of the system is lower than that of MAJ- Δ . Still, these do not explain the Monte Carlo simulation results mentioned earlier.

MAIN FOCUS OF THE CHAPTER

Both the original vN-MUX study and the subsequent theoretical ones have considered unreliable gates. They did not consider the elementary devices, and assumed that the gates have a fixed (bounding) pf_{GATE} . This assumption ignores the fact that *different gates are built using different (numbers of) devices, logic styles, or (novel) technological principles*. While a standard CMOS inverter has 2 transistors, NAND-2 and MAJ-3 have 4 and respectively 10 transistors. Forshaw et al. (2001) suggested that pf_{GATE} could be estimated as:

$$pf_{GATE} = 1 - (1 - \epsilon)^n, \quad (4)$$

where ϵ denotes the probability of failure of a nanodevice (*e.g.*, transistor, junction, capacitor, molecule, quantum dot, etc.), and n is the number of nanodevices a gate has.

Using eq. 4 as $pf_{MAJ-\Delta} = 1 - (1 - \epsilon)^{2\Delta}$ the reliabilities have been estimated by modifying the exact counting results reported in (Beiu et al., 2007). The device-level estimates can be seen in Fig. 2. They show that increasing Δ will not necessarily increase the reliability of MAJ- Δ vN-MUX (over MAJ- Δ). This is happening because MAJ- Δ with larger Δ require more nanodevices. In particular, while MAJ-11 vN-MUX is the best solution for $\epsilon \leq 1\%$ (Fig. 2(a)), it becomes the worst for $\epsilon > 2\%$ (Fig. 2(b)). Hence, larger fan-ins are advantageous for lower ϵ ($\leq 1\%$), while small fan-ins perform better for larger ϵ ($> 1\%$). Obviously, there is a “swapping” region where the ranking is being reversed. We detail Fig. 2(b) for $\epsilon > 1\%$ (Fig. 2(c)) and for the “swapping” region $1\% < \epsilon < 2\%$ (Fig. 2(d), where ‘o’ marks show the envelope). These results imply that increasing Δ and/or

Fig. 2. Probability of failure of MAJ- Δ vN-MUX plotted versus the probability of failure of the elementary (nano)device ε : (a) small ε ($< 1\%$); (b) large ε ($> 1\%$); (c) detail for ε in between 1% and 10%; (d) detailed view of the “swapping” region (ε in between 1% and 2%)

(a)

(b)

(c)

(d)

R_F does not necessarily improve the overall system's reliability. This is because increasing Δ and/or R_F leads to increasing the number of nanodevices:

$$N_{\text{MAJ-}\Delta \text{ vN-MUX}} = R_{\text{MAJ-}\Delta \text{ vN-MUX}} \times n_{\text{MAJ-}\Delta} = 2\Delta \times 2\Delta = 4\Delta^2. \quad (5)$$

This quadratic dependence on Δ has to be accounted for. Basically, it is ε and the number of devices N , and not (only) R_F and pf_{GATE} , which should be used when trying to accurately predict the advantages of vN-MUX—or of any other redundancy scheme.

The next step we took was to compare the device-level estimates of MAJ- Δ vN-MUX (Fig. 3(a)), with the Monte Carlo simulation ones (Fig. 3(b), adapted from (Beiu, 2005) (Beiu & Sulieman, 2006)). The two plots in Fig. 3 have the same vertical scale and exhibit similar shapes. Still, a direct comparison is not trivial as these are mapped against different variables (ε and respectively v). This similarity makes us confident that the estimated results are accurate and supporting the claim that a simple estimate for pf_{GATE} leads to good approximations at the system level. For other insights the interested reader should consult (Anghel & Nicolaidis, 2007) and (Martorell et al., 2007).

FUTURE TRENDS

In a first set of experiments, we compared the reliability of MAJ- Δ with the reliability of MAJ- Δ vN-MUX at $R_F = 2\Delta$. For device-level analyses this is not obvious anymore as MAJ- Δ are not on a 45° line, which makes it hard to understand where and by how much vN-MUX improves over MAJ- Δ . The results of these simulations can be seen in Fig. 4, where we have used the same interval $\varepsilon \in [0, 0.11]$ on the horizontal axis. Here again it looks like the smallest fan-in is the best.

A second set of experiments has studied the effect of changing Δ on the error threshold of MAJ- Δ vN-MUX. Fig. 5(a) shows the theoretical gate-level error thresholds (using eq. (1)), as well as the achievable gate-level error thresholds evaluated based on simulations using the exhaustive counting algorithm. Fig. 5(a) shows that the exact gate-level error thresholds are higher than the theoretical gate-level error threshold values (by about 33%). *It would appear that one could always enhance reliability by going for a larger fan-in.* The extension to device-level estimates can be seen in Fig. 5(b), which reveals a completely different picture. These results imply that:

- device-level error thresholds are about $10\times$ less than the gate-level error thresholds;

- device-level error thresholds are decreasing with increasing to fan-ins (exactly the opposite of gate-level error thresholds);
- for vN-MUX, the highest device-level error threshold of about 4% is achieved when using MAJ-3.

CONCLUSION

This chapter has presented a detailed analysis of MAJ- Δ vN-MUX for very small fan-ins: exact for the gate-level and estimated but accurate for the device-level. The main conclusions are as follows.

- Exact gate-level error thresholds for MAJ- Δ vN-MUX are about 33% better than the theoretical ones and increase with increasing fan-in.
- Estimated device-level error thresholds are about $10\times$ lower than gate-level error thresholds and are decreasing with increasing fan-ins—making smaller fan-ins better (Beiu & Makaruk, 1998), (Ibrahim & Beiu, 2007).
- The abnormal (nonlinear) behavior of vN-MUX (Beiu, 2005), (Beiu & Sulieman, 2006) is due to the fact that the elementary gates are made

Figure 4. Probability of failure of MAJ- Δ and MAJ- Δ vN-MUX plotted versus the device probability of failure ε : (a) $\Delta = 3$; (b) $\Delta = 5$; (c) $\Delta = 7$; (d) $\Delta = 9$. For uniformity, the same interval $\varepsilon \in [0, 0.11]$ was used for all the plots

- of unreliable nanodevices (implicitly accounted for by Monte Carlo simulations, but neglected by theoretical approaches and gate-level simulations).
- Extending the exact gate-level simulations to device-level estimates using $1 - (1 - \varepsilon)^n$, leads to quite accurate approximations (as compared to Monte Carlo simulations).
- Device-level estimates show much more complex behaviors than those revealed by gate-level analyses (nonlinear for large ε , leading to multiple and intricate crossings).
- Device-level estimates suggest that reliability optimizations for large ε will be more difficult than what was expected from gate-level analyses.
- One way to maximize reliability when ε is large and unknown (e.g., time varying (Srinivasan

Figure 5. Error thresholds for MAJ- Δ vN-MUX versus fan-in Δ : (a) gate-level error threshold, both theoretical (red) and exact (yellow) as obtained through exhaustive counting; (b) device-level error threshold

et al., 2005)) is to rely on ‘adaptive’ gates, so neural-inspiration should play a(n important) role in future nano-IC designs (Beiu & Ibrahim, 2007).

Finally, precision is very important as “*small errors ... have a huge impact in estimating the required level of redundancy for achieving a specified/target reliability*” (Roelke et al., 2007). It seems that the current gate-level models tend to underestimate reliability, while we do not do a good job at the device-level, with Monte Carlo simulation the only widely used method. More precise estimates than the ones presented in this chapter are possible using Monte Carlo simulations in combination with gate-level reliability algorithms. These are clearly needed and have just started to be investigated (Lazarova-Molnar et al., 2007).

KEY TERMS

Circuit: Network of devices.

Counting (Exhaustive): The mathematical action of repeated addition (exhaustive considers all possible combinations).

Device: Any physical entity deliberately affecting the information carrying particle (or their associated fields) in a desired manner, consistent with the intended function of the circuit.

Error Threshold: The probability of failure of a component (gate, device) above which the multiplexed scheme is not able to improve over the component itself.

Fan-In: Number of inputs (to a gate).

Fault-Tolerant: The ability of a system (circuit) to continue to operate rather than failing completely (possibly at a reduced performance level) in the event of the failure of some of its components.

Gate (Logic): Functional building block (in digital logic a gate performs a logical operation on its logic inputs).

Majority (Gate): A logic gate of odd fan-in which outputs a logic value equal to that of the majority of its inputs.

Monte Carlo: A class of stochastic (by using pseudorandom numbers) computational algorithms for simulating the behaviour of physical and mathematical systems.

Multiplexing (von Neumann): A scheme for reliable computations based on successive computing stages alternating with random interconnection stages (introduced by von Neumann in 1952).

Redundancy (Factor): Multiplicative increase in the number of (identical) components (subsystems, blocks, gates, devices), which can (automatically) replace (or augment) failing component(s).

Reliability: The ability of a circuit (system, gate, device) to perform and maintain its function(s) under given (as well as hostile or unexpected) conditions, for a certain period of time.

Different Approaches for Cooperation with Metaheuristics

INTRODUCTION

Working on artificial intelligence, one of the tasks we can carry on is optimization of the possible solutions of a problem. Optimization problems appear. In optimization problems we search for the best solution, or one good enough, to a problem among a lot of alternatives.

Problems we try to solve are usual in daily living. Every person constantly works out optimization problems, e.g. finding the quickest way from home to work taking into account traffic restrictions. Humans can find efficiently solutions to these problems because these are easy enough. Nevertheless, problems can be more complex, for example reducing fuel consumption of a fleet of planes. Computational algorithms are required to tackle this kind of problems. A first approach to solve them is using an exhaustive search. Theoretically, this method always finds the solution, but is not efficient as its execution time grows exponentially.

In order to improve this method heuristics were proposed. Heuristics are intelligent techniques, methods or procedures that use expert knowledge to solve tasks; they try to obtain a high performance referring to solution quality and used resources.

Metaheuristics, term first used by Fred Glover in 1986 (Glover, 1986), arise to improve heuristics, and

can be defined as (Melián, Moreno & Moreno, 2003) ‘intelligent strategies for designing and improving very general heuristic procedures with a high performance’. Since Glover the field has been extensively developed. The current trend is designing new metaheuristics that improve the solution to given problems. However, another line, very interesting, is reuse existing metaheuristics in a coordinated system. In this article we present two different methods following this line.

BACKGROUND

Several studies have shown that heuristics and metaheuristics are successful tools for providing reasonably good solutions (excellent in some cases) using a moderate number of resources. A brief look at recent literature (Glover & Kochenberger, 2003), (Hart, Krasnogor & Smith, 2004), (Pardalos & Resende, 2002) reveals the wide variety of problems and methods which appear under the overall topic of heuristic optimization. Within this, obtaining strategies which cooperate in a parallel way is an interesting trend. The interest is on account of two reasons: larger problem instances may be solved, and robust tools, that offer high quality solutions despite variations in the characteristics of the instances, may be obtained.

There are different ways of obtaining this cooperation. One way are ant colony systems (Dorigo & Stützle, 2003) and swarm based methods (Eberhart & Kennedy, 2001) appear as one of the first cooperative mechanisms inspired by nature. Nevertheless, the cooperation principle they have presented to date is too rigid for a general purpose model (Crainic & Toulouse, 2003). Another way are parallel metaheuristics, where very interesting perspectives appear. This is the line we will follow.

There have been huge efforts to parallelize different metaheuristics. Thus we may find synchronic implementations of these methods where the information is shared at regular intervals, (Crainic, Toulouse & Gendreau, 1997) using Tabu Search and (Lee & Lee, 1992) using Simulated Annealing. More recently there have been multi-thread asynchronous cooperative implementations (Crainic, Gendreau, Hansen & Mladenovic, 2004) or multilevel cooperative searches (Baños, Gil, Ortega & Montoya, 2004) which, according to the reports in (Crainic & Toulouse, 2003) provide better results than the synchronic implementations.

However, it seems that a cooperative strategy based on a single metaheuristic does not cover all the possibilities and the use of strategies which combine different metaheuristics is recommended. The paper (Le Bouthillier & Crainic, 2005) is a good example. A whole new area of research opens up. Questions such as, ‘what will be the role of each metaheuristic?’ or ‘What cooperation mechanisms should be used?’ arise.

Within parallel metaheuristics, we will focus following the classification of (Crainic & Toulouse, 2003) on Multi-search metaheuristics, where several concurrent strategies search the solution space. Among them, we concentrate on those techniques, known as Cooperative multi-search metaheuristics, where each strategy exchanges information with the others during the execution.

Cooperative multi-search metaheuristics obtain better quality solutions than independent methods. But previous studies (Crainic & Toulouse, 2002), (Crainic, Toulouse & Sansó, 2004) demonstrate that cooperative methods with a non-restrictive access to shared information may experiment problems of premature convergence. This seems to be due to the stabilization of the shared information, stabilization caused by the intense exchange of the better solutions. So it would be interesting to find a way of controlling this information exchange.

In this context we propose two approaches in order to control the exchange of information, one using memory to cope with this problem, and the other using a process of knowledge extraction.

The first approach (Pelta, Cruz, Sancho-Royo & Verdegay, 2006) proposes a cooperative strategy where a coordinating agent, modelled by a set of ‘ad hoc’ fuzzy rules, receives information from a set of solver agents and sends instructions to each of them telling how to continue. Each solver agent implements the Fuzzy Adaptive Neighbourhood Search (FANS) metaheuristic (Blanco, Pelta & Verdegay, 2002) as a clone. FANS is conceived as an adaptive fuzzy neighbourhood based metaheuristic. Its own characteristics allow FANS to capture the qualitative behaviour of several metaheuristics, and thus, can be considered as a “framework” of metaheuristics.

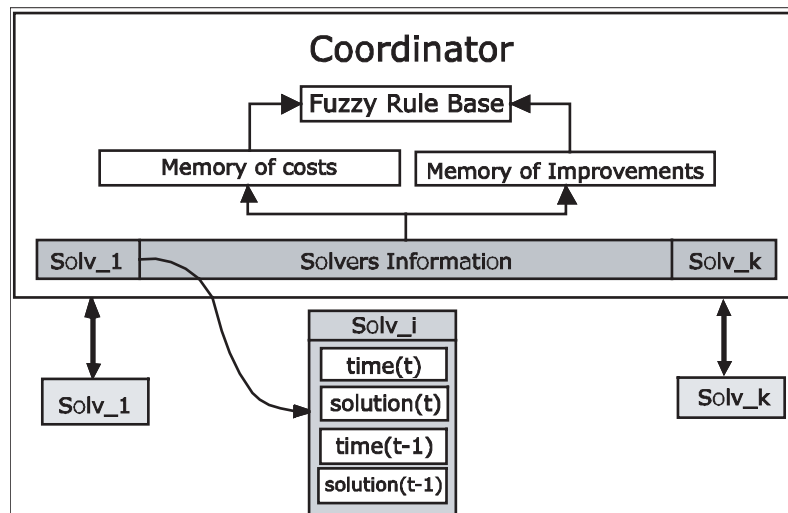

The second approach (Cadenas, Garrido, Liern, Muñoz & Serrano, 2007) uses the same structure but combines a set of different metaheuristics which cooperate within a single coordinated schema, where a coordinating agent modelled by a set of fuzzy rules receives information from the different metaheuristics and sends instructions to each of them. The difference with the previous system lies on the way the rules are obtained. Here, as a result of a knowledge extraction process (Cadenas, Garrido, Hernández & Muñoz, 2006), (Cadenas, Díaz-Valladares, Garrido, Hernández & Serrano, 2006).

TWO COOPERATIVE MULTI-SEARCH METAHEURISTICS

A Cooperative Multi-Search Metaheuristic Using Memory and Fuzzy Rules

The idea of the first strategy can be explained with the help of the diagram in Fig. 1. Given a concrete problem to solve, we have a set of solvers to deal with it. Each solver develops a particular strategy to solve the problem independently, and the whole set of solvers works simultaneously without direct interaction. In order to coordinate the solvers there is a coordinator which knows all the general aspects of the problem concerned and the particular solver features. The coordinator receives reports from the solvers with the obtained results, and returns orders to them.

Figure 1. Diagram of the first strategy

The inner workings of the strategy are quite simple. In the first step, the co-ordinator determines the initial behaviour (set of parameters) for each solver, which models a particular optimization strategy. This behaviour is passed to each solver, which is then executed. For each solver, the co-ordinator keeps the last two reports containing their times, and the corresponding solutions at such times. From the solver information set, the co-ordinator calculates performance measures that will be used to adapt the fuzzy rule base. This fuzzy rule base is generated manually following the principle that *If a solver is working well, keep it; but if a solver seems to be trapped, do something to alter its behaviour.*

Solvers execute asynchronously by sending and receiving information. The co-ordinator checks which solver provided new information and decides whether its behaviour needs to be adapted using the fuzzy rule base. If this is the case, it will obtain a new behaviour and send it to the solvers. Solver operation is quite simple: once execution has begun, performance information is sent and adaptation orders from the coordinator are received alternately.

Each solver thread is implemented by means of the FANS metaheuristic. We use this metaheuristic following three main reasons:

- FANS is essentially a threshold-acceptance local search technique and is therefore easy to understand and implement, and does not require many computational resources.
- FANS can be used as a heuristic template. Each set of parameters implies a different behaviour of the method, and therefore, the qualitative behaviour of other local search techniques can be simulated (Blanco, Pelta & Verdegay, 2002).
- The previous point enables different search schemes to be built, and diversification and intensification procedures to be driven easily. We therefore do not need to implement different algorithms but merely use FANS as a template.

A Cooperative Multi-Search Metaheuristic Using Data Mining to Obtain Fuzzy Rules

The idea of the second strategy is very similar to the first one, and can be seen on Fig. 2. Given a concrete problem to solve, we have a set of solvers to deal with it. Each solver implements a different metaheuristic, and has to solve the problem while coordinates itself with the rest of metaheuristics. In order to perform the cooperation we use a coordinating agent which will con-

Figure 2. Diagram of the second strategy

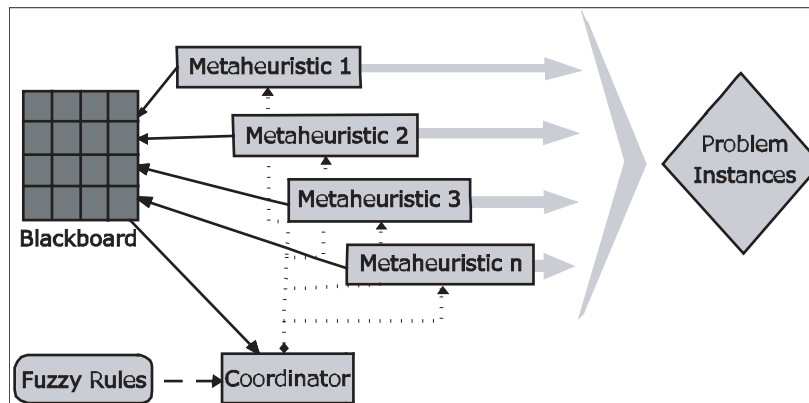

Figure 3. The knowledge extraction process

trol and modify the behaviour of the agents. To perform the communication among the different metaheuristics an adapted blackboard model is used. In this model each agent controls a part of the blackboard where writes its performance information, and periodically updates the solution found. The coordinator consults the blackboard in order to monitor the behaviour of

each metaheuristic and to decide how their behaviour has to be modified.

To give intelligence to the coordinator we propose the use of a set of fuzzy rules obtained as a result of the methodological process proposed on (Cadenas, Garrido, Hernández & Muñoz, 2006), (Cadenas, Díaz-Valladares, Garrido, Hernández & Serrano, 2006), and based on a process of knowledge extraction.

The process of knowledge extraction is shown in (Fig. 3) and divided in the following phases:

1. Preparation of data. In this phase we try to obtain a database containing useful information so that Data Mining could be applied. The metaheuristics that are going to be used in the system are chosen and applied to solve sets of instances of the problem, extracting from these executions interesting data such as the parameters of each metaheuristic or the solutions obtained. After that, it is advisable to apply a preprocess to the database in order to obtain those attributes and instances more relevant
2. Data mining. In the second phase, Data Mining techniques are applied to the information obtained in the previous phase in order to get the model of the system coordinator. Firstly a Data Mining technique is chosen, then is applied to the database and finally using the models obtained, a set of fuzzy rules is deduced.
3. Evaluation. In this phase we test the efficiency of the model of the coordinator, and if it is performing efficiently with regard to computational cost and the solutions obtained.

In this paper we present a synchronous implementation of this model where three metaheuristics are used: a genetic algorithm, a tabu search and a simulated annealing.

The system finally obtained, operates as follows: first, the coordinator sets the initial set of parameters for each metaheuristic, according to the knowledge previously extracted. After that each solver starts its search, periodically all the solvers stop and write their solutions, then the coordinator evaluates them and, using the fuzzy rule base, decides how has to change the solutions and parameters of each metaheuristic. To formulate the rule base we used the knowledge extraction process previously defined whose data mining phase was performed using fuzzy decision trees.

Results Obtained by These Approaches

Once we have studied both systems let us show the results obtained by them. Both strategies were tested solving the knapsack problem, whose mathematical formulation is

$$\max \sum_{j=1}^n p_j \times x_j$$

$$s.t. \sum_{j=1}^n w_j \times x_j \leq C, x_j \in \{0,1\}, j=1, \dots, n$$

where n is the number of items, x_j indicates whether the item j is included in the knapsack or not, p_j is the profit associated with item j , $w_j \in [0, \dots, r]$ is the weight of the item j , and C is the knapsack capacity. We also assume that $w_j < C, \forall j$ (every item fits in the knapsack), and

$$\sum_{j=1}^n w_j > C$$

(the whole set of items does not fit).

We chose knapsack problem because of the fact that we can construct test instances varying hardness according to three characteristics: instance size, type of correlation between weights and profits, and range of the values available for the weights.

We finally carried out the tests with an implementation of each system. The implementation of the memory based system used six solvers, each one implementing FANS with different parameters, and being executed for 30 seconds (Memory based in table 1). The implementation of the data mining based system, as said before, used three solvers, each one implementing a different metaheuristic (a genetic algorithm, a tabu search and a simulated annealing), and being executed for 60 seconds (DM based in table 1). In order to test the performance of the systems we also executed each metaheuristic individually (FANS, Tabu Search, Simulated Annealing, Genetic Algorithm) for 180 seconds.

In table 1 we show the average error obtained for different types and sizes of instances, comparing the Memory based approach with individual FANS, and the DM based with the average results of the three metaheuristics that compose it. As we can see each strategy outperforms its components.

FUTURE TRENDS

After this work several lines of research arise. Related to first strategy, the topic of what kind of information

is stored in the coordinator memory and how this is used to control the global search behavior of the strategy. Related to the second, the knowledge extraction process needs to be improved and tested with different data mining techniques. And to both strategies, the improvement of the fuzzy rule base is another topic to be addressed.

One last consideration is the application field. The knapsack problem is considered one of the “easiest” NP-hard problems, so it would be interesting to apply these strategies to more complex problems such as the p-median, p-hub median or the protein structure comparison.

CONCLUSION

This paper proposes two strategies to cope with convergence problems showed by cooperative multi-search metaheuristics. The first strategy suggests the use of memory in order to define a set of fuzzy rules which control the exchanges of solutions associated to a coordinated schema where similar metaheuristics cooperate. The second strategy proposes the use of a knowledge extraction process to obtain a set of fuzzy rules which control the exchanges of solutions of a coordinated system where different metaheuristics cooperate. Both approaches have been tested and have shown their good performance.

ACKNOWLEDGMENT

The authors thank the “Ministerio de Educación y Ciencia” of Spain and the “Fondo Europeo de Desarrollo

Regional” (FEDER) for the support given to develop this work under the projects TIN2005-08404-C04-01 and TIN2005-08404-C04-02. The three first authors also thank the “Fundación Séneca, Agencia de Ciencia y Tecnología de la Región de Murcia”, which support this research under the “Programa Séneca”. The three second authors also carried out this research in part under project MINAS (TIC-00129).

KEY TERMS

Blackboard: A shared repository of problems, partial solutions, suggestions, and contributed information. The blackboard can be seen as a dynamic “library” of contributions to the current problem that have been recently “published” by other knowledge sources.

Cooperative Multi-Search Metaheuristics: A parallelization strategy for metaheuristics in which parallelism is obtained from multiple concurrent explorations of the solution space and where metaheuristics exchange information during their execution in order to cooperate.

Data Mining: The most characteristic stage of the Knowledge Extraction process, where the aim is to produce new useful knowledge by constructing a model from the data gathered for this purpose.

Fuzzy Rules: Linguistic if-then constructions that have the general form “if A then B” where A and B are collections of propositions containing linguistic variables (A is called the premise and B is the consequence). The use of linguistic variables and fuzzy if-then rules exploits the tolerance for imprecision and uncertainty.

Heuristic: A method or approach that tries to apply expert knowledge in the resolution of a problem with the aim of increasing the probability of solving it.

Knowledge Extraction/Discovery: The non-trivial process of identifying valid, novel, potentially useful and ultimately understandable patterns from large data collections. The overall process and discipline of extracting useful knowledge and includes data warehousing, data cleansing and data manipulation tasks right through to the interpretation and exploitation of results.

Metaheuristic: A high-level strategy for solving a very general class of computational problems by combining user given black-box procedures — usually heuristics — in a hopefully efficient way.

Optimization Problem: A computational problem whose object is to find the best from all feasible solutions.

Parallel Metaheuristics: Metaheuristics in which different threads search concurrently the solution space. They appear naturally in develop of metaheuristics as a way of improving the acceleration factor in the search of solutions.

Problem Instance: A concrete representation of a problem with characteristics that distinguish it from the rest.

Differential Evolution with Self-Adaptation

Janez Brest

University of Maribor, Slovenia

INTRODUCTION

Many practical engineering applications can be formulated as a global optimization problem, in which objective function has many local minima, and derivatives of the objective function are unavailable. Differential Evolution (DE) is a floating-point encoding evolutionary algorithm for global optimization over continuous spaces (Storn & Price, 1997) (Liu & Lampinen, 2005) (Price, Storn & Lampinen, 2005) (Feoktistov, 2006). Nowadays it is used as a powerful global optimization method within a wide range of research areas.

Recent researches indicate that self-adaptive DE algorithms are considerably better than the original DE algorithm. The necessity of changing control parameters during the optimization process is also confirmed based on the experiments in (Brest, Greiner, Bošković, Mernik, Žumer, 2006a). DE with self-adaptive control parameters has already been presented in (Brest et al., 2006a).

This chapter presents self-adaptive approaches that were recently proposed for control parameters in DE algorithm.

BACKGROUND

Differential Evolution

DE creates new candidate solutions by combining the parent individual and several other individuals of the same population. A candidate replaces the parent only if it has better fitness value.

The population of the original DE algorithm (Storn & Price, 1995) (Storn & Price, 1997) contains NP D -dimensional vectors: $\mathbf{x}_{i,G}$, $i = 1, 2, \dots, NP$. G denotes the generation. The initial population is usually selected uniform randomly between the lower and upper bounds. The bounds are specified by the user according to the nature of the problem. After initialization DE performs several vector transforms (operations): mutation, crossover, and selection.

Mutant vector $\mathbf{v}_{i,G}$ can be created by using one of the mutation strategies (Price et al., 2005). The most useful strategy is 'rand/1': $\mathbf{v}_{i,G} = \mathbf{x}_{r1,G} + F \times (\mathbf{x}_{r2,G} - \mathbf{x}_{r3,G})$, where F is the mutation scale factor within range $[0, 2]$, usually less than 1. Indexes $r1, r2, r3$ represent the random and distinct integers generated within range $[1, NP]$, and also different from index i .

After mutation, a 'binary' crossover operation forms the trial vector $\mathbf{u}_{i,G}$, according to the i^{th} population vector and its corresponding mutant vector $\mathbf{v}_{i,G}$:

$$\text{if } (rand \leq CR \text{ or } j = j_{rand}) \text{ then } u_{i,j,G} = v_{i,j,G} \text{ else } u_{i,j,G} = x_{i,j,G},$$

where $i = 1, 2, \dots, NP$ and $j = 1, 2, \dots, D$. CR is the crossover parameter or factor within the range $[0,1]$ and presents the probability of creating parameters for the trial vector from the mutant vector. Uniform random value $rand$ is within $[0, 1]$. Index $j_{rand} \in [1, NP]$ is a randomly chosen index and is responsible for the trial vector containing at least one parameter from the mutant vector.

The selection operation selects, according to the objective fitness value of the population vector $\mathbf{x}_{i,G}$ and its corresponding trial vector $\mathbf{u}_{i,G}$, which vector will survive to be a member of the next generation.

The original DE has more strategies and Feoktistov (Feoktistov, 2006) proposed some general extensions to DE strategies. The question is which strategy is the most suitable to solve a particular problem. Recently some researchers used various combinations of two, three or even more strategies during the evolutionary process.

Parameter Tuning and Parameter Control

Globally, we distinguish between two major forms of setting parameter values: parameter *tuning* and parameter *control* (Eiben, Hinterding & Michalewicz, 1999). The former means the commonly practiced approach that tries to find good values for the parameters before running the algorithm, then tuning the algorithm using

these values, which remain fixed during the run. The latter means that values for the parameters are changed during the run. According to Eiben *et al.* (Eiben *et al.*, 1999) (Eiben & Smith, 2003), the change can be categorized into three classes:

1. *Deterministic parameter control* takes place when the value of a parameter is altered by some deterministic rule.
2. *Adaptive parameter control* is used when there is some form of feedback from the search that is used to determine the direction and/or the magnitude of the change to the parameter.
3. *Self-adaptive parameter control* is the idea that “evolution of the evolution” can be used to implement the self-adaptation of parameters. Here, the parameters to be adapted are encoded into the chromosome (individuals) and undergo the actions of genetic operators. The better values of these encoded parameters lead to better individuals which, in turn, are more likely to survive and produce offspring and, hence, propagate these better parameter values.

DE has three control parameters: amplification factor of the difference vector - F , crossover control parameter - CR , and population size - NP . The original DE algorithm keeps all three control parameters fixed during the optimization process. However, there still exists a lack of knowledge about how to find reasonably good values for the control parameters of DE, for a given function (Liu & Lampinen, 2005).

Although the DE algorithm has been shown to be a simple, yet powerful, evolutionary algorithm for optimizing continuous functions, users are still faced with the problem of preliminary testing and hand-tuning of its control parameters prior to commencing the actual optimization process (Teo, 2006). As a solution, self-adaptation has proved to be highly beneficial for automatically and dynamically adjusting control parameters. Self-adaptation allows an evolutionary strategy to adapt itself to any general class of problem, by reconfiguring itself accordingly, and does this without any user interaction (Bäck, 2002) (Bäck, Fogel & Michalewicz, 1997) (Eiben, Hinterding & Michalewicz, 2003).

RELATED WORK

Work Related to Differential Evolution

The DE (Storn & Price, 1995) (Storn & Price, 1997) algorithm was proposed by Storn and Price, and since then it has been used in many practical cases. The original DE was modified and many new versions have been proposed. Ali and Törn (Ali & Törn, 2004) proposed new versions of the DE algorithm, and also suggested some modifications to the classical DE, in order to improve its efficiency and robustness. They introduced an auxiliary population of NP individuals alongside the original population (noted in (Ali, 2004), a notation using sets is used). Next they proposed a rule for calculating the control parameter F , automatically. Jiao *et al.* (Jiao, Dang, Leung & Hao, 2006) proposed a modification of the DE algorithm, applying a number-theoretical method for generating the initial population, and using simplified quadratic approximation with the three best points. Mezura-Montes *et al.* (Mezura-Montes, Velázquez-Reyes & Coello Coello, 2006) conducted a comparative study of DE variants. They proposed a rule for changing control parameter F at random from interval $[0.4, 1.0]$ at generation level. They used different values of control parameter CR for each problem. The best CR value for each problem was obtained by additional experimentation. Tvrdik in (Tvrdik, 2006) proposed a DE algorithm using competition between different control parameter settings. The prominence of the DE algorithm and its applications is shown in recently published books (Price *et al.*, 2005), (Feoktistov, 2006). Feoktistov in his book (Feoktistov, 2006, p. 18) says, that “the concept of differential evolution is a spontaneous self-adaptability to the function”.

Work Related to Adaptive or Self-Adaptive DE

Liu and Lampinen (Liu & Lampinen, 2005) proposed a version of DE, where the mutation control parameter and the crossover control parameter are adaptive. A self-adaptive DE (SDE) is proposed by Omran *et al.* (Omran, Salman & Engelbrecht, 2005) (Salman, Engelbrecht & Omran, 2007), where parameter tuning is not required. Self-adapting was applied for control

parameters F and CR . Teo (Teo, 2006) made an attempt at self-adapting the population size parameter, in addition to self-adapting crossover and mutation rates. Brest et al. (Brest et al., 2006a) proposed a DE algorithm, using a self-adapting mechanism on the control parameters F and CR . The performance of the self-adaptive differential evolution algorithm was evaluated using a set of benchmark functions provided for constrained real parameter optimization (Brest, Žumer & Sepesy Maučec, 2006b). Qin and Suganthan (Qin & Suganthan, 2005) proposed the “Self-adaptive Differential Evolution algorithm (SaDE), where the choice of learning strategy and the two control parameters F and CR do not require pre-defining. During evolution, suitable learning strategy and parameter settings are gradually self-adapted, according to the learning experience.” Brest et al. (Brest, Bošković, Greiner, Žumer & Sepesy Maučec, 2007) reported performance comparison of certain selected DE algorithms, which use different self-adaptive or adaptive control parameter mechanisms. In this paper the DE algorithms used more than one of the DE strategies (Price et al., 2005), (Feoktistov, 2006). Self-adaptation has been used extensively in evolutionary programming (Fogel, 1995) and evolution strategies (ES) (Bäck & Schwefel, 1993) to adjust the search step size for each objective variable (Liang, Yao & Newton, 2001). Abbass (Abbass, 2002) proposed self-adaptive DE for multi-objective optimization problems.

SELF-ADAPTIVE CONTROL PARAMETERS IN DIFFERENTIAL EVOLUTION

This section presents three Self-Adaptive DE approaches, which has been applied to the control parameters F and CR .

The Self-Adaptive Control Parameters Using Uniform Distribution

The Self-Adaptive DE refers to the self-adapting mechanism on the control parameters, proposed by Brest et al. (Brest et al., 2006a). This self-adapting mechanism used ‘ $rand/1/bin$ ’ strategy. Each individual in the population was extended using the values of two control parameters: $(\mathbf{x}_{i,G}, F_{i,G}, CR_{i,G})$, $i \in 1, 2, \dots$,

NP . Both of the control parameters were applied at individual level.

Brest et al. (Brest et al., 2006a) proposed a self-adaptive DE where new control parameters $F_{i,G+1}$ and $CR_{i,G+1}$ are calculated as follows:

$$\text{if } rand_1 < \tau_1 \text{ then } F_{i,G+1} = F_l + rand_2 \times F_u \text{ else } F_{i,G+1} = F_{i,G},$$

$$\text{if } rand_3 < \tau_2 \text{ then } CR_{i,G+1} = rand_4 \text{ else } CR_{i,G+1} = CR_{i,G},$$

and they produce control parameters F and CR in a new vector. The quantities $rand_j$, $j \in \{1, 2, 3, 4\}$ are uniform random values $\in [0, 1]$. The quantities τ_1 and τ_2 represent the probabilities of adjusting control parameters F and CR , respectively. The parameters τ_1 , τ_2 , F_l , F_u were taken as fixed values 0.1, 0.1, 0.1, 0.9, respectively. The new F takes a value from $[0.1, 1.0]$ in a random manner. The new CR takes a value from $[0, 1]$. The new $F_{i,G+1}$ and $CR_{i,G+1}$ are obtained before the mutation is performed. So they influence the mutation, crossover and selection operations of the new vector $\mathbf{x}_{i,G+1}$.

In (Brest et al., 2006a) a self-adaptive control mechanism was used to change the control parameters F and CR during the evolutionary process. The third control parameter NP was kept unchanged.

Abbass’s Approach

Abbass (Abbass, 2002) proposed Self-adaptive Pareto Differential Evolution (SPDE) algorithm. The SPDE was used for multi-objective optimization problems. New control parameters $F_{i,G+1}$ and $CR_{i,G+1}$ are calculated as follows:

$$F_{i,G+1} = N(0,1),$$

$$CR_{i,G+1} = CR_{r1,G} + N(0,1) \times (CR_{r2,G} - CR_{r3,G}),$$

where $N(0,1)$ is Gaussian distribution. If $F_{i,G+1}$ value is not in $[0, 1]$ then simple rule is used to repair it. And similar for $CR_{i,G+1}$ value. Then mutant vector $\mathbf{v}_{i,G}$ is calculated:

$$\mathbf{v}_{i,G} = \mathbf{x}_{r1,G} + F_{i,G+1} \times (\mathbf{x}_{r2,G} - \mathbf{x}_{r3,G})$$

and crossover operation is performed:

if ($rand \leq CR_{i,G+1}$ or $j = j_{rand}$) then $u_{i,j,G} = v_{i,j,G}$ else
 $u_{i,j,G} = x_{i,j,G}$,

The control parameter CR is self-adapted, by encoding it into each individual.

Approach Proposed by Omran, Salman and Engelbrecht

Due to the success achieved in SPDE by self-adapting CR , Omran et al. (Omran, Salman & Engelbrecht, 2005) (Salman, Engelbrecht & Omran, 2007) proposed a self-adaptive DE (SDE), where the same mechanism is applied to self-adapt the control parameter F . The control parameter CR is generated for each individual from a normal distribution ($CR \sim N(0.5, 0.15)$) in SDE and the mutation operation changes as follows:

$$\mathbf{v}_{i,G} = \mathbf{x}_{r1,G} + F_{i,G+1} \times (\mathbf{x}_{r2,G} - \mathbf{x}_{r3,G}),$$

where

$$F_{i,G+1} = F_{r4,G} + N(0, 0.5) \times (F_{r5,G} - F_{r6,G}).$$

Indexes $r4, r5, r6$ represent the random and distinct integers generated within range $[1, NP]$. Thus, each individual i has its own control parameter F_i which is calculated as a stochastic linear combination of the control parameters of randomly selected individuals.

The presented self-adapting mechanisms on the control parameters F and CR , use 'rand/1/bin' strategy. Both of the control parameters are applied at individual level. The third control parameter NP remains fixed during the evolutionary process.

FUTURE TRENDS

The behaviour of DE is influenced by values of its parameters (F, CR, NP). During last two decades a lot of papers addressed the problem of finding insight concerning the behaviour of the algorithm (Zaharie, 2002). The theory of DE is still behind the empirical studies. The theoretical studies of DE are highly desirable as future researches.

It is not an easy task for one optimization algorithm to be both fast (e.g. it needs a small number of function

evaluations) and robust (e.g. it does not get trapped in local optimum) at the same time. Based on our experiences (other authors reported similar observations) with the DE algorithm, we can conclude that DE provides more robustness if the population size is higher. If the population size is increased, on the other hand, more computational power (on average) is needed. The population size is an important control parameter, and thus adaptive and/or self-adaptive approaches on this parameter are expected in the future.

In this chapter only the 'rand/1/bin' DE strategy is used, but the DE algorithm has more strategies (Price et al., 2005), (Feoktistov, 2006). Which combination of (self-adaptive) DE strategies should someone use to get the best performances. One can use the involved strategy with the same probability, or with different probability, or even use a self-adaptation to choose the most suitable strategy during the optimization process.

Future work may also be directed towards testing the proposed self-adaptive versions of the DE algorithm, especially on constrained optimization problems. Multi-objective optimization is also a challenge for future work.

CONCLUSION

This chapter carried out differential evolution (DE) algorithm with focus on the self-adaptive control parameters. Three self-adaptive approaches, which were recently proposed in literature, are described in the chapter. The presented approaches have control parameters applied at individual level. If we look in literature, the self-adaptive versions of the DE algorithm usually gave better performance results in comparison to the original DE algorithm. We can conclude that self-adaptation can improve the performance of the DE algorithm and this powerful global optimization algorithm could be used over a wide-range of research areas in the future.

KEY TERMS

Area of the Search Space: Set of specific ranges or values of the input variables that constitute a subset of the search space.

Control Parameter: Control parameter determines behaviour of evolutionary program (e.g. population size).

Differential Evolution: An evolutionary algorithm for global optimization, which realized the evolution of a population of individuals in a manner that uses of differences between individuals.

Evolutionary Computation: Solution approach guided by biological evolution, which begins with potential solution models, then iteratively applies algorithms to find the fittest models from the set to serve as inputs to the next iteration, ultimately leading to a model that best represents the data.

Individual: An individual represents a candidate solution. During the optimization process an evolutionary algorithm usually uses a population of individuals to solve a particular problem.

Search Space: Set of all possible situations of the optimization problem that we want to solve.

Self-Adaptation: The ability that allows an evolutionary algorithm to adapt itself to any general class of problems, by reconfiguring itself accordingly, and do this without and user interaction.

Discovering Mappings Between Ontologies

INTRODUCTION

Knowledge Representation is important part of AI. The purpose is to reveal best possible representation of the Universe of Discourse (UoD) by capturing entities, concepts and relations among them. With increased understanding of various scientific and technological disciplines, it is possible to derive rules that governs the behaviour and outcome of the entities in the UoD. In certain cases, it is not possible to establish any explicit rule, yet through experience or observation, some experts can define rules from their tacit knowledge in specific domain.

Knowledge representation techniques are focused on techniques that allows externalization of implicit and explicit knowledge of expert(s) with a goal of reuse in absence of physical presence of such expertise. To ease this task, two parallel dimensions have developed over period of time. One dimension is focused on investigating more efficient methods that best suit the knowledge representation requirement resulting in theories and tools that allows capturing the domain knowledge (Brachman & Levesque, 2004). Another development has taken place in harmonization of tools and techniques that allows standard based representation of knowledge (Davies, Studer, & Warren, 2006).

Various languages are proposed for representation of the knowledge. Reasoning and classification algorithms are also realized. As an outcome of standardization process, standards like DAML-OIL (Horrocks & Patel-Schneider, 2001), RDF (Manola & Miller, 2004) and OWL (Antoniou & Harmelen, 2004) are introduced. Capturing the benefit of both developments, the tooling is also came in to existence that allows creation of knowledgebase.

As a result of these developments, the amount of publicly shared knowledge is continuously increasing. At the time of this writing, a search engine like Swoogle (Ding et al., 2004)-developed to index publicly available

Ontologies, is handling over 2,173,724 semantic web documents containing 431,467,096 triples.

While the developments are yielding positive results by such a huge amount of knowledge available for reuse, it have become difficult to select and reuse required knowledge from this vast pool. The concepts and their relations that are important to the given problem could have already been defined in multiple Ontologies with different perspectives with specific level of details. It is very likely that to get complete representation of the knowledge, multiple Ontologies must be utilized. This requirement has introduced a new discipline within the domain of knowledge representation that is focused on investigation of techniques and tools that allows integration of multiple shared Ontologies.

BACKGROUND

The problem of Ontology integration is not completely new. Schema Matching is a similar problem being addressed in the context of enterprise integration. But, in Ontology matching, the scale and complexity is much higher and requires special considerations. (Shvaiko & Euzenat, 2006) highlights the key similarities and differences between both the techniques. In schema matching, the semantics of the given term is guessed whereas the ontology matching methods relies on deriving the semantics from explicit representation of concepts and relations in given Ontology. Numerous methods and approaches have been proposed that attempt to solve the problem targeting specific aspects of the represented knowledge (Ehring, 2007).

Apart from standards that guide the languages used for the development of Ontology, some standard Ontologies have also been defined. The role of these Ontologies is to provide framework of vary basic elements and their relations, based on which complex domain knowledge can be developed. SUO (Niles & Pease,

2001), SUMA(Niles & Pease, 2003), OpenCyc(Sicilia et al., 2004) are examples of the same. SWEET(Raskin, 2003) provides standard Ontologies in environmental science domain. Hence, the levels in Ontology also address important dimension in knowledge engineering through integrating available Ontologies.

ONTOLOGY MAPPING TECHNIQUES

Research in integration of multiple Ontologies have resulted in various techniques and tools that have successfully demonstrated capabilities in producing the required results(Noy, 2004b). The ontology integration is addressed as Ontology mapping, matching, merging, transforming and other such activities. The integration is achieved by focusing on finding similarities among the concepts of separate Ontologies. The similarity or nearness can be established by employing various techniques, and numerous such approaches have been published demonstrating the suitability of single or hybrid approaches. The taxonomic overview of existing methodology is provided in many survey papers that provides a reasonable entry in to the domain of Ontology integration. (Kalfoglou et al., 2005) provides comprehensive survey of Ontology mapping approach and classify them on Semantic Intensity Spectrum. (Noy, 2004a) (Kalfoglou & Schorlemmer, 2005) and (Predoiu et al., 2006) provides comprehensive survey discussing state-of-the-art of present research efforts.

Ontologies consists of concepts and elements. The integration process that establishes the similarity among concepts consists of three dimensions (Shvaiko & Euzenat, 2006). The input dimension is related to underlying data model and can operate at schema level or instance level. Second is the process dimension that classifies approach as exact or approximate determination. Third dimension deals with output in the form of Cardinality, type of relation and the confidence. Integration can be done by identification of Alignment.

Concept Level Approaches

Concept level approaches are restricted only to the name of the concept and employ various methods to match whole or part of the concept names that belong to different Ontologies. Though these syntax oriented approaches proves to be less efficient when applied in isolation, they are generally employed in pre-integra-

tion preparation phase (or normalization phase) of more complex semantic oriented approaches. Many of the Schema Matching techniques are directly applicable for concept level approaches.

String Level Concept Matching

It is based on the simple assumption that concept having similarity is represented with same name in different Ontologies. Upon identification of such string level similarity the source Ontologies can either mapped or merged. PROMPT(Noy & Musen, 2000) Ontology Merging tool employs string level concept matching approach.

Sub-String Level Concept Matching

Approaches that brakes the input concepts in to smaller segments on the basis of prefix, suffix and other structures. Another approach establishes the similarity by identifying the *Edit Distance*. For example if Nikon and NKN are under consideration, the Edit Distance is a number of insertion, deletion and substitution of characters that will be required in Nikon and NKN to transform one into the other. N-gram technique is employed for deriving a set of substrings by selecting n number of characters from input string. For example trigram of NIKON results in NIK, IKO and KON. The derived set can further be subjected to simple string matcher for finding similarities.

Lexical Matching

Lexical approaches are employed to identify and extract tokens from the input string. This is particularly useful when concept name are created using mix of alphanumeric characters that can be processed to separate operators, numbers, punctuations and other types of token to reveal processable substrings. LOM(Li, 2004)- a Lexicon based Ontology Mapping tool employs strategy to determine similarity by matching the whole term, word constituent, synset, and type matching (Choi et al., 2006). OLA(Euzenat et al., 2005) and Cupid(Madhavan et al., 2001) also employs lexical techniques for finding similarity among concepts.

Linguistic Similarity Approach

Natural Language Processing domain offers various text processing techniques such as stemming, tokenization, tagging, elimination, expansion etc. that can improve result of similarity finding effort. Usage and grammar of language may result in mismatch for example, like Product and Products, in such cases Lemmatization can be used. Tokenization that can remove grammatical elements from concept name can be utilized. Unnecessary articles, Preposition, conjunction and other features can be removed using Elimination technique. Lexical relation can be also identified using sense based approach by exploring Hypernyms, hyponyms etc. in WordNet(Miller, 1995). HCONE-Merge(Kotis et al., 2006) is a Ontology merging approach that uses Latent Semantic Analysis (LSA) technique and carryout lookup WordNet and by expanding word sense by hyponymy. Domain or Application specific terminology can also be integrated for disambiguation. Cupid - a schema matching approach-employs linguistic matching in its initial phase. Quick Ontology Mapping (Ehrig & Sure, 2005) employs finding of linguistic similarity of concepts. ASCO(Le et al., 2004) technique calculate linguistic similarity as a linear combination of name, label and description similarity of concepts.

Semantic Concept Matching Approach

iMAP(Dhamankar et al., 2004) employs semantic matching for integration of heterogeneous data sources. It addresses 1-1 and complex matches among concepts. The multiple search approach toward identification of matches, utilizes domain knowledge for improving schema matching accuracy. S-Match (Giunchiglia et al., 2005) derives semantic matching between two graph structures. MAFRA (Maedche et al., 2002) (MApping FRamework) employs Semantic Bridge and Service Centric approach.

Pairs

By transforming the input Ontologies into directed labelled graph, the Similarity Flooding techniques generates Pair-wise Connectivity Graphs (PCG) where a node consists of a pair or matching elements from the sources. The technique further assigns weights to the edges indicating how well the similarity of given pair propagates to the neighbours.

Structure Level Approaches

Approaches that considers the ontology in graph structure and consider upper and lower levels of the given concepts to find out similarity among concepts of different Ontologies.

Structural Similarity

COMA(Aumueeller et al., 2005) system employs path similarity as a basis for calculating similarity among concept. SMART tool employs algorithm that considers structure of the relation in the vicinity of the concept being processed. It is implemented with PROMPT system that can be plugged in with Protégé-a widely accepted open-source knowledge engineering tool. Anchor-PROMPT(Noy & Musen, 2001) extends the simple PROMPT by calculating similarity measures based on ontology structure.

Semantic Matching

S-Match focuses on computing semantic matching between graph structures extracted from separate Ontologies. With this technique it is possible to differentiate the meaning of Concept of node and Concept at node.

Lattice

FCA-Merge(Stumme, 2005) incorporates machine learning Technique to derive a lattice which is then used to derive merged Ontology. Documents are accepted as inputs that provides the concepts to build the Ontology.

Machine Learning and Statistics Based Approach

While determination of exact mapping achieved by establishing string and structure level similarities, the performance can be further improved by employing methods to approximate the nearness. Machine learning, probability and statistics techniques can be incorporating in mapping techniques to improve the performance and achieving automation in matching process. GLUE(Doan et al., 2002) employs an instance based machine learning technique to semi-automatically create mappings for input Ontologies. Concept

Similarity in terms of joint probability distribution of instances of given concept. Ontology Mapping Enhancer (OMEN) (Mitra et al., 2005) adopts generation of Bayesian Net on the basis of mappings defined a priori. ITTalk (Cost et al., 2002) adopts Bayesian reasoning along with text based classification technology that collects similarity information in source Ontologies. The discovered semantic similarity is codified as labels and arcs of a graph.

Community Oriented Approach

CAIMAN (Lacher & Groh, 2001) proposed a scenario where member of communities want to express their viewpoints on categorization in community repository. COMA++ (Aumüller et al., 2005) offers community driven ontology mapping by providing support for web based acquisition and sharing of ontology mapping.

Logic Based Approach

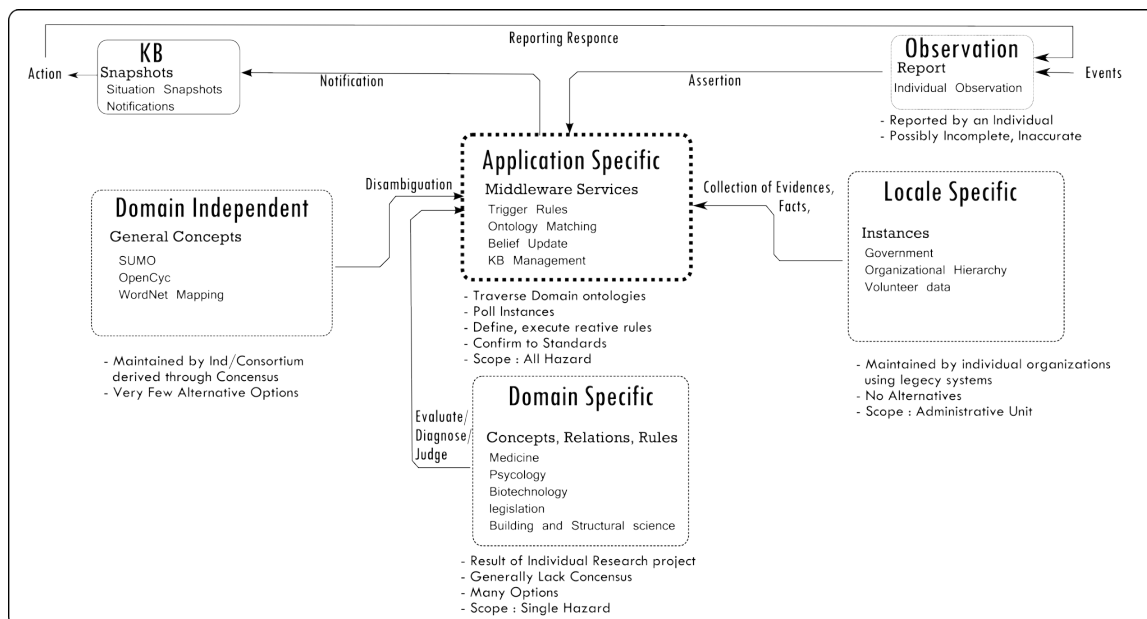

Description Logic (DL) is widely accepted for knowledge representation task. It is observed that Ontology creation is commonly carried out with commonly used tools that supports OWL-DL representation and reasoning. The mapping language that is selected to represent

mapping can also benefit from the representation and reasoning capability of DL. MAFRA (Maedche et al., 2002) uses DL for representing Semantic Bridge Ontology (SBO). OntoMapO uses DL for creating a Meta Ontology for consistent representation of Ontologies and mapping among them. CTXMatch and S-Match employs satisfiability techniques that is achieved using DL. ConcepTool (Compatangelo & Meisel, 2003) system uses DL in formalizing class-centered enhanced entity relationship model.

FUTURE TRENDS

Organizations are increasingly adopting knowledge-based approaches in building systems. The Ontology mapping techniques discussed here provides overview of efforts that enables integration of multiple Ontologies in the context of targeted application. Along with the syntax and standardized content, it will become necessary to consider Ontologies with various levels of detail to be mapped for complete and accurate coverage. Extending the current approaches that take a few Ontologies as input selected from vast pool based on the availability of required elements or structures, it will be necessary to consider specific types of Ontol-

Figure 1. Ontology mediation requirement in future applications

ogy. Figure 1 indicates one of the challenging open problems of investigating appropriate methods that allows integration of Ontologies defining Domain Independent, Domain Specific, Local Specific and Application Specific concepts to provide complete coverage of knowledge representation. This approach ensures that knowledge engineers can reuse the integrated part of Domain Independent and Domain Specific concepts and focus on only local specific concept to suitably integrate with application being built. For explaining a example scenario Figure 1 indicates the Ontology integration required for Disaster Management Agencies across the world. The Domain Specific and Domain Independent concepts are required by every agency and can be directly integrated with local specific and application specific concepts that can be unique to each implementing agency.

CONCLUSION

With proliferation of knowledge representation and reasoning techniques and standard based tools, domain knowledge captured in the form of Ontology is increasingly being available for reuse. The quality and quantity and level of detail with which domain concepts are defined differ considerably based on the discretion of knowledge engineer. The reuse requires concepts defined in multiple such Ontologies to be extracted or mapped to a resulting comprehensive representation that suits the requirement of problem on hand. This in-turn introduce the problem of syntactic and semantic heterogeneity. This article provided state-of-the-art in present techniques targeted at resolving heterogeneity.

KEY TERMS

Articulation Ontology: Articulation ontology consists of concepts and relations that are identified

as link among the concepts defined in two separate Ontologies also known as articulation rules.

Context Aware Techniques: Techniques that are focused on nearness of weight assigned to specific relations among concepts considering application context as basis for mapping.

Extension Aware Techniques: Techniques that are focused on finding nearness among features of available instances of different Ontologies to form basis for mapping.

Intension Aware Techniques: Based on the Information flow theory, techniques that are focused on finding two different tokens (instances) belonging to separate Ontologies that maps to single type (concept) as a basis for mapping.

Linguistic Similarity Techniques: Set of techniques that refer linguistic nearness of concepts in the form of synonyms, hypernyms, and hyponyms by referring to related entries in the thesaurus as basis for mapping.

Ontology Alignment: Ontology Alignment is a process to articulate similarity in the form of one-to-one equality relation between every elements of two separate Ontologies.

Ontology Integration: Ontology Integration is a process that results in generation of a new ontology derived as a union of two or more source Ontologies of different but related subject domain.

Ontology Mapping: Ontology Mapping is a process to articulate similarities among the concepts belonging to separate source Ontologies.

Ontology Mediation: Ontology mediation is a process that reconciles difference between separate Ontologies to achieve semantic interoperability by performing alignment, mapping, merging and other required operations.

Ontology Merging: Ontology Mapping is a process that results in generation of a new ontology derived as a union of two or more source Ontologies of same subject domain.

Semantic Similarity Techniques: Techniques that are focused on logic satisfiability as basis of mapping.

String Similarity Techniques: Set of techniques that uses syntactic similarity of concepts as basis of mapping.

Structure Aware Techniques: Techniques that also consider structural hierarchy of concepts as basis of mapping.

Disk-Based Search

University of Dortmund, Germany

INTRODUCTION

The need to deal with large data sets is at the heart of many real-world problems. In many organizations the data size has already surpassed Petabytes (10^{15}). It is clear that to process such an enormous amount of data, the physical limitations of RAM is a major hurdle. However, the media that can hold huge data sets, i.e., hard disks, are about a 10,000 to 1,000,000 times slower to access than RAM. On the other hand, the costs for large amounts of disk space have considerably decreased. This growing disparity has led to a rising attention to the design of *external memory algorithms* (Sanders et al., 2003) in recent years.

In a hard disk, random disk accesses are slow due to disk latency in moving the head on top of the data. But once the head is at its proper position, data can be read very rapidly. External memory algorithms exploit this fact by processing the data in the form of blocks. They are more informed about the future accesses to the data and can organize their execution to have minimum number of block accesses.

Traditional graph search algorithms perform well as long as the graph can fit into the RAM. But for large graphs these algorithms are destined to fail. In the following, we will review some of the advances in the field of search algorithms designed for large graphs.

BACKGROUND

Most modern operating systems provide a general-purpose memory management scheme called *Virtual Memory* to compensate for the limited RAM. Unfortunately, such schemes pay off only when the algorithm's memory accesses are local, i.e., it works on a particular memory address range for a while, before switching the attention to another range. Search algorithms, especially those that order the nodes on some

particular node property, do not show such behaviour. They jump back and forth to pick the best node, in a spatially unrelated way for only marginal differences in the node property.

External memory algorithms are designed with a hierarchy of memories in mind. They are analyzed on an *external memory model* as opposed to the traditional von Neumann RAM model. We use the two-level memory model by Vitter and Shriver (1994) to describe the search algorithms. The model provides the necessary tools to analyze the asymptotic number of block accesses (I/O operations) as the input size grows. It consists of

- M : Size of the internal memory in terms of the number of elements,
- $N \gg M$: Size of the input in terms of the number of elements, and
- B : Size of the data block that can be transferred between the internal memory and the hard disk; transferring one such block is called as a single I/O operation.

The complexity of external memory algorithms is conveniently expressed in terms of predefined I/O operations, such as, *scan*(N) for scanning a file of size N with a complexity of $\Theta(N/B)$ I/Os, and *sort*(N) for external sorting a file of size N with a complexity of $\Theta(N/B \log_{M/B}(N/B))$ I/Os. With additional parameters the model can accommodate multiple disks and multiple processors too.

In the following, we assume a graph as a tuple (V, E, c) , where V is the set of nodes, E the set of edges, and c the weight function that assigns a non-zero positive integer to each edge. If all edges have the same weight, the component c can be dropped and the graphs are called as *unweighted*. Given a start node s and a goal node g , we require the search algorithm to return an optimal path wrt. the weight function.

EXTERNAL MEMORY SEARCH ALGORITHMS

External Memory Breadth-First Search

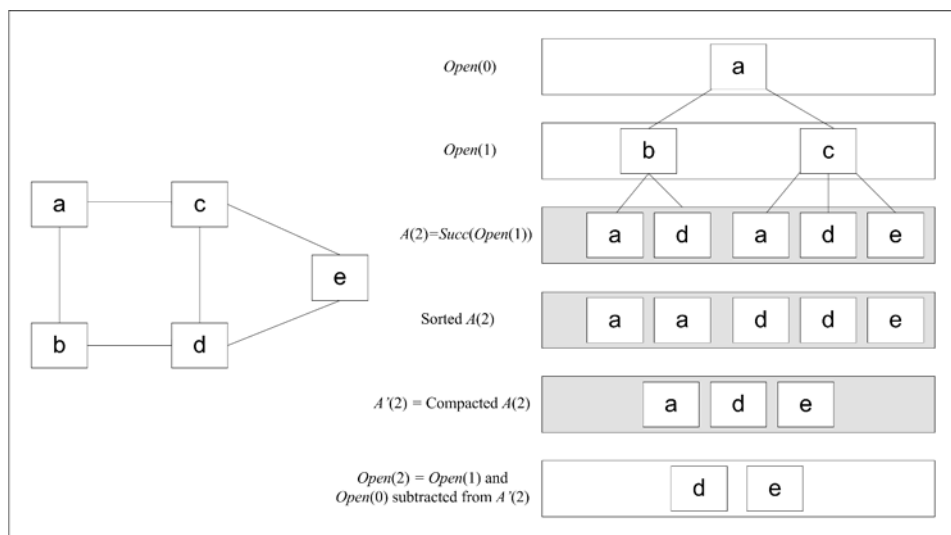

Breadth-first search (BFS) is one of the basic search algorithms. It explores a graph by first expanding the nodes that are closest to the start node. BFS for external memory has been proposed by Munagala and Ranade (1999). It only considers undirected and explicit (provided beforehand in the form of adjacency lists) graphs. The working of the algorithm is illustrated on a graph in Fig. 1. Let $Open(i)$ be the set of nodes at BFS level i residing on disk. The algorithm builds $Open(i)$ from $Open(i-1)$ as follows. Let $Succ(Open(i-1))$ be the multi-set of successors of nodes in $Open(i-1)$; this set is created by concatenating all adjacency lists of nodes in $Open(i-1)$. As there can be multiple copies of the same node in this set the next step is to remove these duplicate nodes. In an internal memory setting this can be done easily using a hash table. Unfortunately, in an external setting a hash-table is not affordable due to random accesses to its contents. Therefore, we rely on alternative methods of duplicates' removal that are well-suited for large data on disk. The first step is to sort the successor set using external sorting algorithms resulting in duplicate nodes lying adjacent to each

other. By an external scanning of this sorted set, all duplicates are removed. Still, there can be nodes in this set that have already been expanded in the previous layers. Munagala and Ranade proved that for undirected graphs, it is sufficient to subtract only two layers, $Open(i-1)$ and $Open(i-2)$, from $Open(i)$. Since all three lists are sorted, this can be done by a parallel external scanning. The accumulated I/O complexity of this algorithm is $O(|V| + sort(|E|))$ I/Os, where $|V|$ is for the unstructured access to the adjacency lists, and $sort(|E|)$ for duplicates removal.

An implicit graph variant of the above algorithm has been proposed by Korf (2003). It applies $O(sort(|Succ(Open(i-1))|) + scan(|Open(i-1)| + |Open(i-2)|))$ I/Os in each iteration. Since no explicit access to the adjacency list is needed (as the state space is generated on-the-fly), by using $\sum_i |Succ(Open(i))| = O(|E|)$ and $\sum_i |Open(i)| = O(|V|)$, the total execution time is bounded by $O(sort(|E|) + scan(|V|))$ I/Os.

To reconstruct a solution path, we may store predecessor information with each node on disk (thus doubling the state vector size). Starting from the goal node, we recursively search for its predecessor in the previous layer through external scanning. The process continues until the first layer containing the start node is reached. Since the Breadth-first search preserves the shortest paths in a uniformly weighted graph, the

Figure 1. An example graph (left); Stages of External Breadth-First Search (right). Each horizontal bar corresponds to a file. The grey-shaded $A(2)$ and $A'(2)$ are temporary files.

constructed path is the optimal one. The complexity is bounded by the scanning time of all layers in consideration, i.e., by $O(\text{scan}(|V|))$ I/Os.

External Memory Heuristic Search

Heuristic search algorithms utilize some form of guidance; be it user-provided or automatically inferred from the problem structure, to hone in on the goal. In practice, such algorithms are very effective when compared with the blind search algorithms like BFS. A* (Hart et al., 1968) is one such algorithm that prioritizes the nodes based on their actual distance from the start node along with their heuristic estimate to the goal state. Formally, if $g(n)$ represents the path cost for reaching a node n , and $h(n)$ the heuristic estimate of reaching the goal starting from n , then A* orders the nodes based on their f -value defined as $f(n)=g(n)+h(n)$. For an efficient implementation of A*, a priority queue data structure is required that allows us to remove the node with the minimum f -value for expansion. If the heuristic function h is *consistent*, then on each search path, no successor will have a smaller f -value than the predecessor. Therefore, A* – traversing the node set in f -order – expands each node at most once.

*External A** by Edelkamp et al. (2004) maintains the search frontier on disk as files. Each file corresponds to an external representation of a bucket-based priority queue data structure. A *bucket* is a set of nodes sharing common properties. In a 1-level bucket implementation of A* by Dial (1969) each bucket addressed with index i contains all nodes u that have priority $f(u)=i$. A refinement proposed by Jensen et al. (2002) distinguishes between nodes with different g -values, and designates bucket $Open(i,j)$ to all nodes n with path length $g(n)=i$ and heuristic estimate $h(n)=j$. An external memory representation of this data structure memorizes each bucket in a different file. During the exploration process, only nodes from $Open(i,j)$ with $i+j=f$ are expanded, up to its exhaustion. Buckets are selected in lexicographic order for (i,j) . By that time, the buckets $Open(i',j')$ with $i'<i$ and $i'+j'=f$ are *closed*, whereas the buckets $Open(i',j')$ with $i'+j'>f$ or with $i'>i$ and $i'+j'=f$ are *open*. Depending on the expansion progress, nodes in the active bucket are either *open* or *closed*.

It is practical to pre-sort buffers in one bucket immediately by an efficient internal sorting algorithm to ease merging. Duplicates within an active bucket are eliminated by merging all the pre-sorted buffers cor-

responding to the same bucket, resulting in one sorted file. This file can then be scanned to remove the duplicate nodes from it. In fact, both the merging and removal of duplicates can be done simultaneously. Another case of the duplicate nodes appears, when the nodes that have already been evaluated in the upper layers are generated again. As in the algorithm of Munagala and Ranade, External A* exploits the observation that, in an undirected problem graph, duplicates of a node with BFS-level i can at most occur in levels i , $i-1$ and $i-2$. In addition, since h is a total function, we have $h(n) = h(n')$, if $n = n'$. These duplicate nodes can be removed by file subtraction for the next active bucket $Open(g+1, h-1)$. We remove any node that has appeared in buckets $Open(g, h-1)$ and $Open(g-1, h-1)$. This file subtraction can be done by a mere parallel scan of the pre-sorted files and by using a temporary file in which the intermediate result is stored. It suffices to perform the duplicate removal only for the bucket that is to be expanded next.

Duplicate Detection Scope

The number of previous layers that are sufficient for full duplicate detection in directed graphs, is dependent on a property of the search graph called *locality* (Zhou and Hansen, 2006). In the following, we generalize their concept to weighted and directed search graphs. For a problem graph with node set V , discrete cost function c , successor set $Succ$, initial state s , and δ being defined as the minimal cost between two states, the shortest-path locality is defined as $L = \max \{ \delta(s, n) - \delta(s, n') + c(n, n') \mid n, n' \in V, n' \in Succ(n) \}$. In unweighted graphs, we have $c(n, n')=1$ for all n, n' . Moreover, $\delta(s, n)$ and $\delta(s, n')$ differ by at most 1, so that the locality is 2, which is consistent with the observation of Munagala and Ranade.

The locality determines the *thickness* of the search frontier needed to prevent duplicates from appearing in the search. While the locality is dependent on the graph, the duplicate detection scope also depends on the search algorithm applied. For BFS, the search tree is generated with increasing path lengths (number of edges), while for weighted graphs the search tree is generated with increasing path cost (this corresponds to Dijkstra's algorithm in the one-level bucket priority queue data structure).

In a positively weighted search graph, the number of buckets that need to be retained to prevent duplicate

search effort is equal to the shortest-path locality of the search graph. Let us consider two nodes n and n' , with $n' \in \text{Succ}(n)$. Assume that n has been expanded for the first time, generating the successor n' which has already appeared in the layers $0, \dots, \delta(s, n) - L$ implying $\delta(s, n') \leq \delta(s, n) - L$. We have, $L \geq \delta(s, n) - \delta(s, n') + c(n, n') \geq \delta(s, n) - (\delta(s, n) - L) + c(n, n') = L + c(n, n')$, in contradiction to $c(n, n') > 0$.

Refinements

Improvements of Munagala and Ranade's algorithm for explicit undirected graphs have been proposed by Mehlhorn and Meyer (2002), where a more structured access to the adjacency lists has been proposed. Ajwani et al. (2007) present an extensive empirical comparison of these approaches on different kinds of graphs.

Hash-based delayed duplicate detection (Korf and Schultze, 2005) is designed to avoid the complexity of sorting. It is based on two orthogonal hash functions. The primary hash function distributes the nodes to different files. Once a file of successors has been generated, duplicates are eliminated. The assumption is that all nodes with the same primary hash address fit into main memory. The secondary hash function maps all duplicates to the same hash address.

Structured duplicate detection (Zhou and Hansen, 2004) builds up an abstract graph on top of the problem graph through a disjoint partitioning. For expansion, all states that are mapped to the same abstract node are loaded into the memory along with the nodes that are mapped to the neighbouring abstract nodes. The partition is defined in such a way that any two adjacent nodes in the graph are mapped either to the same partition or to a neighbouring abstract partition. The successor nodes are checked against the neighbouring partitions and are removed if found as duplicates, as soon as they are generated.

Applications

Implementations for external *model checking* algorithms have been proposed by Kristensen and Mailund (2003), who suggested a sweep-line technique for scanning the search space according to a given partial order. For general LTL (Linear Temporal Logic) model checking, Edelkamp and Jabbar (2006) have extended External A* for *safety* and *liveness* checking and integrated it into the state-of-the-art model checker, SPIN.

FUTURE TRENDS

It is often the case that external memory algorithms can be lifted to parallel algorithms. With the advent of multi-core processors and affordable PC clusters, parallel algorithms become more and more important. Jabbar and Edelkamp (2006) provide a parallel implementation of the External A* for model checking safety properties. For probabilistic and non-deterministic models *value iteration* (VI) has been extended by Edelkamp et al. (2007) to work on large state spaces that cannot fit into the RAM. Instead of working on states, it works on edges $(n, n', a, h(n'))$, where n is called the predecessor state, n' the stored state, a the action that transforms n into n' , and $h(n')$ is the current value for n' . Similarly to the internal version of VI, the external version of VI works in two phases. A forward phase, where the state space is generated, and a backward phase, where the heuristic values are repeatedly updated until an ϵ -optimal policy is computed, or a maximum iterations are performed.

CONCLUSION

We have presented a brief overview of disk-based search algorithms. These algorithms are especially designed for large graphs that cannot fit into the RAM. An external variant of one of the basic search algorithms, i.e., Breadth-first search has been introduced. For the domains where a search algorithm can be equipped with some form of guidance to reduce the search efforts, External A* provides a complete and I/O efficient extension of the famous A* search algorithm. The whole paradigm of disk-based search is largely dependant on alternate forms of duplicate detection schemes. The most general one is sorting-based delayed duplicate detection. For special problems where a good disjoint partitioning of the graph is possible, hash-based duplicate detection and structured duplicated detection are feasible choices. We have also presented a generalization of the duplicate detection scope that dictates the number of previous layers that have to be checked to guarantee that no node will be expanded twice. Finally, we saw some future trends directed towards an efficient utilization of modern multi-core hardware and to policy search methods.

STXXL (Dementiev et al., 2005) provides an efficient library for external memory data structures and algorithms.

KEY TERMS

Delayed Duplicate Detection: In difference to hash tables that eliminate duplicate states on-the-fly during the exploration, the process of duplicate detection can be delayed until a large set of states is available. It is very effective in external search, where it is efficiently achieved by external sorting and scanning.

Graph: A set of nodes connected through edges. The node at the head of an edge is called as the *target* and at the tail as the *source*. A graph can be *undirected*, i.e., it is always possible to return to the source through the same edge – the converse is a *directed* graph. If given beforehand in the form of adjacency lists (e.g., a road network), we call it an *explicit* graph. *Implicit* graphs – another name for ‘state spaces’ – are generated on-

the-fly from a start node and a set of rules/actions to generate the new states (e.g., a checkers game).

Heuristic Function: A function that assigns a node, an estimated distance to the goal node. For example, in route-planning, the Euclidean distance can be used as a heuristic function. A heuristic function is *admissible*, if it never overestimates the shortest path distance. It is also *consistent*, if it never decreases on any edge more than the edge weight, i.e., for a node n and its successor n' , $h(n) - h(n') \leq c(n, n')$.

Memory Hierarchy: Modern hardware has a hierarchy of storage mediums: starting from the fast registers, the L1 and L2 caches, moving towards RAM and all the way to the slow hard disks and tapes. The latency timings on different levels differ considerably, e.g., registers: 2ns, cache: 20ns, hard disk: 10ms, tape: 1min.

Model Checking: It is an automated process that when given a model of a system and a property specification, checks if the property is satisfied by the system or not. The properties requiring that '*something bad will never happen*' are referred as *safety* properties, while the ones requiring that '*something good will eventually happen*' are referred as *liveness* properties.

Search Algorithm: An algorithm that when given two graph nodes, *start* and *goal*, returns a sequence of nodes that constitutes a path from *start* to the *goal*, if such a sequence exists. A search algorithm generates the successors of a node through an *expansion* process, after which, the node is termed as a *closed* node. The newly generated successors are checked for duplicates, and when found as unique, are added to the set of *open* nodes.

Value Iteration: Procedure that computes a policy (mapping from states to action) for a probabilistic or non-deterministic search problem most frequently in form of a Markov Decision Problem (MDP).

Distributed Constraint Reasoning

Marius C. Silaghi

Makoto Yokoo

Kyushu University, Japan

INTRODUCTION

Distributed constraint reasoning is concerned with modeling and solving naturally distributed problems. It has application to the coordination and negotiation between semi-cooperative agents, namely agents that want to achieve a common goal but would not give up private information over secret constraints. When compared to centralized constraint satisfaction (CSP) and constraint optimization (COP), one of the most expensive operations is communication. Other differences stem from new coherence and privacy needs. We review approaches based on asynchronous backtracking and depth-first search spanning trees.

Distributed constraint reasoning started as an outgrowth of research in constraints and multi-agent systems. Take the sensors network problem in Figure 1, defined by a set of geographically distributed sensors that have to track a set of mobile nodes. Each sensor can watch only a subset of its neighborhood

at a given time. Three sensors need to simultaneously focus on the same mobile node in order to locate it. Approaches modeling and solving this problem with distributed constraint reasoning are described in (Bejar, Domshlak, Fernandez, Gomes, Krishnamachari, Selman, & Valls, 2005).

There are two large classes of distributed constraint problems. The first class is described by a set of *Boolean relations* (aka *constraints*) on possible assignments of variables, where the relations are distributed among agents. They are called distributed constraint satisfaction problems (DisCSPs). The challenge is to find assignments of variables to values such that all these relations are satisfied. However, the reasoning process has to be performed by collaboration among the agents. There exist several solutions to a problem, and ties have to be broken by some priority scheme. Such priorities may be imposed from the problem description where some agents, such as government agencies, are more important than others. In other problems it is important to ensure that different solutions or participants have equal chances, and this property is called *uniformity*. When no solution exists, one may still want to find an assignment of the variables that conflict as few constraints as possible. The second class of problems refers to numerical optimization described by a set of functions (*weighted constraints*) defined on assignments of variables and returning positive numerical values. The goal is to find assignments that minimize the objective function defined by the sum of these functions. The problems obtained in this way are called distributed constraint optimization problems (DisCOPs). Some problems require a fair distribution of the amount of dissatisfaction among agents, minimizing the dissatisfaction of the most unsatisfied agent.

There are also two different ways of distributing a problem. The first way consists of distributing the data associated with it. It is defined in terms of which agents know which constraints. It can be shown that any

Figure 1. Sensor network

such problem can be translated into problems where all non-shared constraints are *unary* (constraints involving only one variable), also called *domain constraints*. Here one can assume that there exists a single unary constraint for each variable. It is due to the fact that any second unary constraint can be reformulated on a new variable, required to be equal to the original variable. The agent holding the unique domain constraint of a variable is called the *owner of that variable*. Due to the availability of this transformation many solutions focus on the case where only the unary constraints are not shared by everybody (also said to be private to the agents that know them). Another common simplification consists in assuming that each agent has a single unary constraint (i.e., a single variable). This simplification does not reduce the generality of the addressable problems since an agent can participate in a computation under several names, e.g., one instance for each unary constraint of the original agent. Such false identities for an agent are called pseudo-agents (Modi, Shen, Tambe, & Yokoo, 2005), or abstract agents (Silaghi & Faltings, 2005).

The second way of distributing a problem is in terms of who may propose instantiations of a variable. In such an approach each variable may be assigned a value solely by a subset of the agents while the other agents are only allowed to reject the proposed assignment. This distribution is similar to restrictions seen in some societies where only the parliament may propose a referendum while the rest of the citizens can only approve or reject it. Approaches often assume the simultaneous presence of both ways of distributing the problem. They commonly assume that the only agent that can make a proposal on a variable is the agent holding the sole unary constraint on that variable, namely its owner (Yokoo, Durfee, Ishida, & Kuwabara, 1998). When several agents are allowed to propose assignments of a variable, these authorized agents are called *modifiers* of that variable. An example is where each holder of a constraint on a variable is a legitimate modifier of that variable (Silaghi & Faltings, 2005).

BACKGROUND

The first challenge addressed was the development of *asynchronous algorithms* for solving distributed problems. Synchronization forces distributed processes to run at the speed of the slowest link. Algorithms that do

not use synchronizations, namely where participants are at no point aware of the current state of other participants, are flexible but more difficult to design. With the exception of a few *solution detection* techniques (Yokoo & Hirayama, 2005), (Silaghi & Faltings, 2005), most approaches gather the answer to the problem by reading the state of agents after the system becomes idle and reaches the so called *quiescence* state (Yokoo et al., 1998). Algorithms that eventually reach quiescence are also called *self-stabilizing* (Collin, Dechter, & Katz, 1991). A *complete* algorithm is an algorithm that guarantees not to miss any existing solution. A *sound* algorithm is a technique that never *terminates* in a suboptimal state.

Another challenge picked by distributed constraint reasoning research consists of providing privacy for the sub-problems known by agents (Yokoo et al., 1998). The object of privacy can be of different types. The *existence of a constraint* between two variables may be secret as well as the *existence of a variable* itself. Many approaches only try to ensure the *secrecy of the constraints*, i.e., the hiding of the identity of the *valuations* that are penalized by that constraint. For optimization problems one also assumes a need to keep secret the amount of the penalty induced by the constraint. As mentioned previously, it is possible to model such problems in a way where all secret constraints are unary (approach known as having *private domains*). Some problems may have both secret and public constraints. Such public constraints may be used for an efficient preprocessing prior to the expensive negotiation implied by secret constraints. Solvers that support guarantees of privacy at any cost employ *cryptographic multi-party computations* (Yao 1982). There exist several cryptographic technologies for such computations, and some of them can be used interchangeably by distributed problem solvers. However, some of them offer information theoretical security guarantees (Shamir, 1979) being resistant to any amount of computation, while others offer only cryptographic security (Cramer, Damgaard, & Nielsen, 2000) and can be broken using large amounts of computation or quantum computers. The result of a computation may reveal secrets itself and its damages can be reduced by being careful in formulating the query to the solver. For example, less information is lost by requesting the solution to be picked randomly than by requesting the first solution. The computations can be done cryptographically by a group of *semi-trusted servers*,

or they can be performed by participants themselves. A third issue in solving distributed problems is raised by the size and the dynamism of the system.

DISTRIBUTED CONSTRAINT REASONING

Framework

A common definition of a distributed constraint optimization problem (DisCOP) (Modi et al., 2005) consists of a set of variables $X=\{x_1, \dots, x_n\}$ and a set of agents $A=\{A_1, \dots, A_n\}$, each agent A_i holding a set of constraints. Each variable x_i can be assigned only with those values which are allowed by a domain constraint D_i . A constraint Φ_j on a set of variables X_j is a function associating a positive numerical value to each combination of assignments to the variables X_j . The typical challenge is to find an assignment to the variables in X such that the sum of the values returned by the constraints of the agents is minimized.

A tuple of assignments is also called a *partial solution*. A restriction often used with DisCOPs requires that each agent A_i holds only constraints between x_i and a subset of the previous variables, $\{x_1, \dots, x_{i-1}\}$. Also, for any agent A_p , the agents $\{A_1, \dots, A_{p-1}\}$ are the

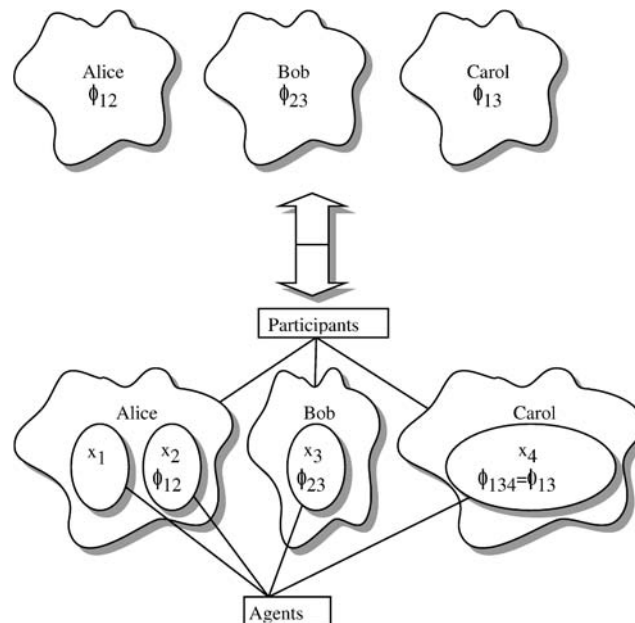

predecessors of A_i and the agents $\{A_{i+1}, \dots, A_n\}$, are its successors.

To understand the generality and limitations of this restriction, consider a conference organization problem with 3 variables x_1 (time), x_2 (place), and x_3 (general chair) and 3 constraints Φ_{12} (between x_1 and x_2), Φ_{23} (between x_2 and x_3), and Φ_{13} (between x_1 and x_3), where Alice has Φ_{12} , Bob enforces Φ_{23} , and Carol is interested in Φ_{13} , Figure 3.

This problem can be modeled as a DisCOP with 4 agents. Alice uses two agents, A_1 and A_2 . The original participant is called physical agent and the agents of the model are called pseudo-agents. Bob uses the agent A_3 and Carol uses an agent A_4 . The new variable x_4 of the agent A_4 is involved in a ternary constraint Φ_{134} with x_1 and x_3 . The constraint Φ_{134} is constructed such that its projection on x_1 and x_2 is Φ_{13} .

However the restricted framework cannot help general purpose algorithms to learn and exploit the fact that agents A_1 and A_2 know each other's constraints. It also requires finding an optimal value for the variable x_4 , which is irrelevant to the query. To avoid aforementioned limitations some approaches remove the restriction on which variables can be involved in the constraints of an agent and can obtain some improvements in speed

Figure 2. Translating between DisCOP frameworks

(Silaghi & Faltings, 2005). Other frameworks typically used with hill-climbing solvers, with solvers that reorder agents, and with arc consistency, assume that each agent A_i knows all the constraints that involve the variable x_i . This implies that any constraint between two variables x_i and x_j is known by both agents A_i and A_j . In general, a problem modeled as a DisCOP where any private constraint may be held by any agent can be converted to its dual representation in order to obtain a model with this framework. When penalties for constraint violation can only take values in $\{0, \infty\}$, corresponding to $\{true, false\}$, one obtains distributed constraint satisfaction problems.

A *protocol* is a set of rules about what messages may be exchanged by agents, when they may be sent, and what may be contained in their payload. A *distributed algorithm* is an implementation of a protocol as it specifies an exact sequence of operations to be performed as a response to each event, such as start of computation or receipt of a message. Autonomous self-interested agents are more realistically expected to implement protocols rather than to strictly adhere to algorithms. Protocols can be theoretically proved correct. However experimental validation and efficiency evaluation of a protocol is done by assuming that agents strictly follow some algorithm implementing that protocol.

Efficiency Metrics

The simplest metric for evaluating DisCOP solvers uses the time from the beginning of a distributed computation to its end. It is possible only with a real distributed system (or a very realistic simulation). The network load for benchmarks is evaluated by counting the total number of messages exchanged or the total number of bytes exchanged. The total time taken by a simulator yields the efficiency of a DisCOP solver when used as a weighted CSP solver. Another common metric is given by the *highest logic clocks* (Lamport, 1978) occurring during the computation. Lamport's logic clocks associate a cost with each message and another cost with each local computation. When the cost assigned to each message is 1 and the cost for local computations is 0, the obtained value gives the *longest sequential chain of causally ordered messages* (Silaghi & Faltings, 2005). When all message latencies are identical, this metric is equivalent to the number of rounds of a simulator where at each round an agent handles all messages received in the previous round (Yokoo et al., 1998).

If the cost assigned to each message is 0 and the cost of a constraint check is 1, the obtained value gives the number of *non-concurrent constraint checks* (NCCC) (Meisels, Kaplansky, Razgon, & Zivan, 2002). When a constraint check is assumed to cost a fraction of a message then the obtained value gives the *equivalent NCCCs* (ENCCCs). One can evaluate the actual fraction between message latencies and constraint checks in the operating point (OP) of the target application (Silaghi & Yokoo, 2007). However many distributed solvers do not check constraints directly but via *nogoods* and there is no standardized way of accounting the handling of the latter ones.

Techniques

Solving algorithms span the range between full centralization, where all constraints are submitted to a central server that returns a solution, through incremental centralization (Mailler & Lesser, 2004), to very decentralized approaches (Walsh, Yokoo, Hirayama, & Wellman, 2003).

The Depth-First Search (DFS) spanning trees of the constraint graph proves useful for distributed DisCOP solvers. When used as a basis for ordering agents, the assignment of any node of the tree makes its subtrees independent (Collin, Dechter, & Katz, 2000). Such independence increases parallelism and decreases the complexity of the problem. The structure can be exploited in three ways. Subtrees can be explored in parallel for an opportunistic evaluation of the best branch, reminding of iterative A* (Modi et al., 2005). Alternatively a branch and bound approach can systematically evaluate different values of the root for each subtree (Checheta & Sycara, 2006). A third approach uses dynamic programming to evaluate the DFS trees from leaves towards the root (Petcu & Faltings, 2006).

Asynchronous usage of *lookahead* techniques based on maintenance of *arc consistency* and *bound consistency* require handling of interacting data structures corresponding to different concurrent computations. Concurrent consistency achievement processes at different depths in the search tree have to be coordinated giving priority to computations at low depths in the tree (Silaghi & Faltings, 2005).

The concept at the basis of many asynchronous algorithms is the *nogood*, namely a self contained statement about a restriction to the valuations of the

variables, inferred from the problem. A *generalized valued nogood* has the form $[R, c, T]$ where T specifies a set of partial solutions $\{N_p, \dots, N_k\}$ for which the set of constraints R specifies a penalty of at least c . A common simplification, called *valued nogood* (Dago & Verfaillie, 1996), refers to a single partial solution, $[R, c, N]$. Priority induced vector clock timestamps called *signatures* can be used to arbitrate between conflicting assignments concurrently proposed by several modifiers (Silaghi & Faltings, 2005). They can also handle other types of conflicting proposals, such as new ordering.

ADOPT-ing is an illustrative algorithm unifying the basic DisCSP and DisCOP solvers ABT (Yokoo et al., 1998) and ADOPT (Modi et al., 2005). It works by having each agent concurrently chose for its variable the best value given known assignments of *predecessors* and cost estimations received from *successors* (Silaghi & Yokoo 2007). Each agent announces its assignments to interested successors using **ok?** messages. Agents are interested in variables involved in their constraints or nogoods. When a nogood is received, agents announce new interests using **add-link** messages. A forest of DFS trees is dynamically built. Initially each agent is a tree, having no ancestors. When a constraint is first used, the agent adds its variables to his *ancestors* list and defines his *parent* in the DFS tree as the closest ancestor. Ancestors are announced of their own new ancestors. Nogoods inferred by an agent using resolution on its nogoods and constraints are sent to targeted predecessors and to its parent in the DFS tree using **nogood** messages, to guarantee optimality. Known costs of DFS subtrees for some values can be announced to those subtrees using **threshold** nogoods attached to **ok?** messages.

Example

An asynchronous algorithm could solve the problem in Figure 2 using the trace in Figure 3. In the messages of

Figure 3. The constraint graph of a DisCOP. The fact that the penalty associated with not satisfying the constraint $x_1 \neq x_2$ is 4, is denoted by the notation (#4).

Figure 3, constraints are represented as Boolean values in an array. The i^{th} value in this array set to T signifies that the constraints of A_i are used in the inference of that nogood. The agents start selecting values for their variables and announce them to interested lower priority agents. The first exchanged messages are **ok?** messages sent by A_1 to both successors A_2 and A_3 and proposing the assignment $x_1=1$. A_2 sends an **ok?** message to A_3 proposing $x_2=2$.

A_3 detects a conflict with x_1 , inserts A_1 in its DFS tree ancestors list, and sends a nogood with cost 2 to A_1 (message 3). A_1 answers the received nogood by switching its assignment to a value with lower current estimated value, $x_1=2$ (message 4). A_2 reacts by switching x_2 to its lowest cost value, $x_2=1$ (message 5). A_3 detects a conflict with x_2 and inserts A_2 in its ancestors list, which becomes $\{A_1, A_2\}$. A_3 also announces the conflict to A_2 using the **nogood** message 6. This nogood received by A_2 is combined with the nogood locally inferred by A_2 for its value 2 due to the constraint $x_1 \neq x_2$ (#4). That inference also prompts the insertion of A_1 in the ancestors list of A_2 . The obtained nogood is therefore sent to A_1 using message 7. A_1 and later A_2 switch their assignments to the values with the lowest cost, attaching the latest nogoods received for those values as threshold nogoods (messages 8, 9 and 10). At this moment the system reaches *quiescence*.

FUTURE TRENDS

The main remaining challenges with distributed constraint reasoning are related to efficient ways of achieving privacy and with handling very large problems.

CONCLUSION

The distributed constraint reasoning paradigms allow easy specification of new problems. The notion varies largely between almost any two researchers. It can refer to the distribution of subproblems or it can refer to the distribution of authority in assigning variables. The reason and goals of the distribution vary as well, where either privacy of constraints, parallelism in computation, or size of data are cited as major concern. Most algorithms can be easily translated from one framework to the other, but they may not be appropriate for a new goal.

KEY TERMS

Agent: A participant in a distributed computation, having its own constraints.

Constraint: A relation between variables specifying a subset of their Cartesian product that is not permitted. Optionally it can also specify numeric penalties for those tuples.

DisCOP: Distributed Constraint Optimization Problem framework (also DCOP).

DisCSP: Distributed Constraint Satisfaction Problem framework (also DCSP).

Nogood: A logic statement about combinations of assignments that are penalized due to some constraints.

Optimality: The quality of an algorithm of returning only solutions that are at least as good as any other solution.

Quiescence: The state of being inactive. The system will not change without an external stimulus.

Distributed Representation of Compositional Structure

Simon D. Levy

Washington and Lee University, USA

INTRODUCTION

AI models are often categorized in terms of the connectionist vs. symbolic distinction. In addition to being descriptively unhelpful, these terms are also typically conflated with a host of issues that may have nothing to do with the commitments entailed by a particular model. A more useful distinction among cognitive representations asks whether they are *local* or *distributed* (van Gelder 1999).

Traditional symbol systems (grammar, predicate calculus) use local representations: a given symbol has no internal content and is located at a particular address in memory. Although well understood and successful in a number of domains, traditional representations suffer from brittleness. The number of possible items to be represented is fixed at some arbitrary hard limit, and a single corrupt memory location or broken pointer can wreck an entire structure.

In a distributed representation, on the other hand, each entity is represented by a pattern of activity distributed over many computing elements, and each computing element is involved in representing many different entities (Hinton 1984). Such representations have a number of properties that make them attractive for knowledge representation (McClelland, Rumelhart, & Hinton 1986): they are robust to noise, degrade gracefully, and support graded comparison through distance metrics. These properties enable fast associative memory and efficient comparison of entire structures without unpacking the structures into their component parts.

This article provides an overview of distributed representations, setting the approach in its historical context. The two essential operations necessary for building distributed representation of structures – *binding* and *bundling* – are described. We present example applications of each model, and conclude by discussing the current state of the art.

BACKGROUND

The invention of the backpropagation algorithm (Rumelhart, Hinton, & Williams 1986) led to a flurry of research in which neurally inspired models were applied to tasks for which the use of traditional AI data structures and algorithms were commonly assumed to be the only viable approach. A compelling feature of these new models was that they could “discover” the representations best suited to the modelling domain, unlike the manmade representations used in traditional AI. These discovered or learned representations were typically vectors of numbers in a fixed interval like $[0, 1]$, representing the values of the hidden variables. A statistical technique like principal component analysis could be applied to such representations, revealing interesting regularities in the training data (Elman 1990).

Issues concerning the nature of the representations learned by backpropagation led to criticisms of this work. The most serious of these held that neural networks could not arrive at or exploit systematic, compositional representations of the sort used in traditional cognitive science and AI (Fodor & Pylyshyn 1988). A minimum requirement noted by critics was that a model that could represent e.g. the idea *John loves Mary* should also be able to represent *Mary loves John* (systematicity) and to represent *John*, *Mary*, and *loves* individually in the same way in both (compositionality). Critics claimed that neural networks are in principle unable to meet this requirement.

Systematicity and compositionality can be thought of as the outcome of two essential operations: *binding* and *bundling*. Binding associates fillers (*John*, *Mary*) with roles (lover, beloved). Bundling combines role/filler bindings to produce larger structures. Crucially, representations produced by binding and bundling must support an operation to recover the fillers of roles: it must be possible to ask “Who did what to whom?” questions and get the right answer. Starting

around 1990, several researchers began to focus their attention on building models that could perform these operations reliably.

VARIETIES OF DISTRIBUTED REPRESENTATION

This article describes the various approaches found in the recent neural network literature to implementing the binding and bundling operations. Although several different models have been developed, they fall into one of two broad categories, based on the way that roles are represented and how binding and bundling are performed.

Recursive Auto-Associative Memory

In Recursive Auto-Associative Memory, or RAAM (Pollack 1990), fillers are represented as relatively small vectors ($N=10$ -50 elements) of zeros and ones. Roles are represented as $N \times N$ matrices of real values, and role/filler binding as the vector/matrix product. Bundling is performed by element-wise addition of the resulting vectors. There are typically two or three role matrices, representing general role categories like agent and patient, plus another $N \times N$ matrix must to represent the predicate (*loves*, *sees*, *knows*, etc.). Because all vectors are the same size N , vectors containing bindings can be used as fillers, supporting structures of potentially unlimited complexity (*Bill knows Fred said John loves Mary*.) The goal is to learn a set of matrix values (weights) to encode a set of such structures.

In order to recover the fillers, a corresponding set of matrices must be trained to *decode* the vectors produced by the encoder matrices. Together, the encoder and decoder matrices form an autoassociator network (Ackley, Hinton, & Sejnowski 1985) that can be trained with backpropagation. The only additional constraint needed for backprop is that the vector/matrix products be passed through a limiting function, like the sigmoidal “squashing” function $f(x) = 1 / (1 + e^{-x})$, whose output falls in the interval (0,1). Figure 1 shows an example of autoassociative learning for a simple hypothetical structure, using three roles, with $N = 4$. The same network is shown at different stages of training (sub-tree and full tree) during a single backprop epoch. Note that the network devises its own compositional representations on its intermediate (“hidden”) layer, based on arbitrary binary vectors chosen by the experimenter. Unlike these binary vectors (black and white units), the intermediate representations can have values between zero and one (greyscale).

Once the RAAM network has learned a set of structures, the decoder sub-network should be able to recursively unpack each learned representation into its constituent elements. As shown in Figure 2, decoding is a recursive process that terminates when the decoder’s output is similar enough to a binary string and continues otherwise. In the original RAAM formulation, “similar enough” was determined by thresholds: if a unit’s value was above 0.8, it was considered to be on, and if it was below 0.2 it was considered to be off.

RAAM answered the challenge of showing how neural networks could represent compositional structures in a systematic way. The representations discovered by RAAM could be compared directly via distance metrics,

Figure 1. Learning the structure (*knows bill (loves john mary)*) with RAAM

and transformed in a rule-like way, without having to recursively decompose the structure elements as in traditional localist models (Chalmers 1990). Nevertheless, the model failed to scale up reliably to data sets of more than a few dozen different structures. This limitation arose from the termination test, which created a variety of “halting problem”: decoding often terminated too soon or continued indefinitely. In addition, encodings of novel structures were typically decoded to already-learned structures, a failure in generalization.

A number of solutions were developed to deal with this problem. One solution (Levy and Pollack 2001) built on the insight that the RAAM decoder is essentially an iterated function system, or IFS (Barnsley 1993). Use of the sigmoidal squashing function ensures that this IFS has an attractor, which is the infinite set (Cantor dust) of vectors reachable on an infinite number of feedback iterations from any initial vector input to the decoder. A more “natural” termination test is to check whether the output is a member of the set of vectors that make up this attractor. Fixing the numerical precision of the decoder results in a finite number of representable vectors, and a finite time to reach the attractor, so that membership in the attractor can be determined efficiently.

This approach to the termination test produced a RAAM decoder that could store a provably infinite number of related structures (Melnik, Levy, & Pollack 2001). Because the RAAM network was no longer an autoassociator, however, it was not clear what sort of algorithm could replace backpropagation for learning a specific, finite set of structures.

The other solution to the RAAM scaling problem discarded the nonlinear sigmoidal squashing function and replaced backprop with principal components

analysis (PCA) as a means of learning internal representations (Callan 1996). This approach yielded the ability to learn a much larger set of structures in many fewer iterations (Voegtlin & Dominey 2005), and showed generalization similar in some respects to what has been observed for children acquiring a first language (Tomasello 1992).

Vector Symbolic Architectures

Vector Symbolic Architectures is a term coined by Gayler (2003) for a general class of distributed representation models that implement binding and bundling directly, without an iterative learning algorithm of the sort used by RAAM. These models can trace their origin to the Tensor Product model of Smolensky (1990). Tensor-product models represent both fillers and roles as vectors of binary or real-valued numbers. Binding is implemented by taking the tensor (outer) product of a role vector and a filler vector, resulting in a mathematical object (matrix) having one more dimension than the filler. Given vectors of sufficient length, each tensor product will be unique. As with RAAM, bundling can then be implemented as element-wise addition (Figure 3), and bundled structures can be used as roles, opening the door to recursion. To recover a filler (role) from a bundled tensor product representation, the product is simply divided by the role (filler) vector.

Because the dimension of the tensor product increases with each binding operation, this method suffers from the well-known “curse of dimensionality” (Bellman 1961). As more recursive embedding is performed, the size of the representation grows exponentially. The solution is to collapse the $N \times N$ role/filler matrix back into a length- N vector. As shown

Figure 2. Decoding a structure to its constituents

in Figure 4, there are two ways of doing this. In Binary Spatter Coding, or BSC (Kanerva 1994), only the elements along the main diagonal are kept, and the rest are discarded. If bit vectors are used, this operation is the same as taking the exclusive or (XOR) of the two vectors. In Holographic Reduced Representations, or HRR (Plate 1991), the sum of each diagonal is taken, with wraparound (circular convolution) keeping the length of all diagonals equal. Both approaches use very large ($N > 1000$ elements) vectors of random values drawn from a fixed set or interval.

Despite the size of the vectors, VSA approaches are computationally efficient, requiring no costly backpropagation or other iterative algorithm, and can be done in parallel. Even in a serial implementation, the BSC approach is $O(N)$ for a vector of length N , and the HRR approach can be implemented using the Fast

Fourier Transform, which is $O(N \log N)$. The price paid is that most of the crucial operations (circular convolution, vector addition) are a form of lossy compression that introduces noise into the representations. The introduction of noise requires that the unbinding process employ a “cleanup memory” to restore the fillers to their original form. The cleanup memory can be implemented using Hebbian auto-association, like a Hopfield Network (Hopfield 1982) or Brain-State-in-a-Box model (Anderson, Silverstein, Ritz, & Jones 1977). In such models the original fillers are attractor basins in the network’s dynamical state space. These methods can be simulated by using a table that stores the original vectors and returns the one closest to the noisy version.

FUTURE TRENDS

Both the RAAM and VSA approaches have provided a basis for a significant amount of research in AI and cognitive science. The invention of the simplified linear RAAM, trained by relatively fast iterative method using principal components (Voegtlin & Dominey 2005) makes RAAM a practical approach to representing structure in distributed representation. Recent work in modelling language acquisition (Dominey, Hoen, & Inui 2006) hints at the possibility that RAAM may continue to thrive in its linear incarnation.

On the other hand, the simplicity of the VSA approach, using vector arithmetic operations available as primitives in many programming environments, has made it increasingly popular for modelling a variety of cognitive tasks – especially those requiring the integration of different types of information. For example, the DRAMA analogy model of Eliasmith & Thagard (2001) shows how HRR be used to integrate semantic and structural information in a way that closely parallels results seen in analogy experiments with human subjects. HRR has also been successfully applied to representing word order and meaning in a unified way, based on exposure to language data (Jones & Mewhort 2007).

CONCLUSION

This article has presented two popular methods for representing structured information in a distributed way: Recursive Auto-Associative Memory (RAAM) and Vector Symbolic Architectures (VSA). The main difference between the two approaches lies in the way that representations are learned: RAAM uses an iterative algorithm to converge on a single stable representation for a set of structures, whereas VSA assembles structures in a “one-shot” learning stage, but the representation of each such structure must be stored separately. While no single approach is likely to solve all or even most of the challenges of AI, there is little doubt that the advantages provided by distributed representations – robustness to noise, fast comparison without decomposition, and other psychologically realistic features – will continue to make them attractive to anyone interested in how the mind works.

D

KEY TERMS

Binary Spatter Codes (BSC): VSA using bit vectors and element-wise exclusive-or (XOR) or multiplication for role/filler binding.

Binding: In its most general sense, a term used to describe the association of values with variables. In AI and cognitive science, the variables are usually a closed set of roles (*AGENT, PATIENT, INSTRUMENT*) and the values an open set of fillers (entities).

Bundling: VSA operation for combining several items into a single item, through vector addition.

Cleanup Memory: Mechanism required to compensate for noise introduced by lossy compression in VSA.

Distributed Representation: A general method of representing and storing information in which the representation of each item is spread across the entire memory, each memory element simultaneously stores the components of more than one item, and items are retrieved by their content rather than their address.

Holographic Reduced Representation (HRR): The most popular variety of VSA, uses circular convolution to bind fillers to roles and circular correlation to recover the fillers or roles from the bindings.

Recursive Auto-Associative Memory (RAAM): Neural network architecture that uses vector/matrix multiplication for binding and iterative learning to encode structures.

Tensor Products: Early form of VSA that uses the outer (tensor) product as the binding operation, thereby increasing the dimensionality of the representations without bound.

Vector Symbolic Architecture (VSA): General term for representations that use large vectors of random numbers for roles and fillers, and fast, lossy compression operations to bind fillers to roles.

EA Multi-Model Selection for SVM

INTRODUCTION

Evolutionary algorithms (**EA**) (Rechenberg, 1965) belong to a family of stochastic search algorithms inspired by natural evolution. In the last years, EA were used successfully to produce efficient solutions for a great number of hard optimization problems (Beasley, 1997). These algorithms operate on a population of potential solutions and apply a survival principle according to a **fitness** measure associated to each solution to produce better approximations of the optimal solution. At each iteration, a new set of solutions is created by selecting individuals according to their level of fitness and by applying to them several operators. These operators model natural processes, such as selection, recombination, mutation, migration, locality and neighborhood. Although the basic idea of **EA** is straightforward, solutions coding, size of population, fitness function and operators must be defined in compliance with the kind of problem to optimize.

Multi-class problems with binary **SVM** (Support Vector Machine) classifiers are commonly treated as a decomposition in several binary sub-problems. An open question is how to properly choose all models for these sub-problems in order to have the lowest error rate for a specific SVM multi-class scheme. In this paper, we propose a new approach to optimize the **generalization capacity** of such SVM multi-class schemes. This approach consists in a global selection of models for sub-problems altogether and is denoted as **multi-model selection**. A multi-model selection can outperform the classical individual model selection used until now in the literature, but this type of selection defines a hard optimisation problem, because it corresponds to a search

a efficient solution into a huge space. Therefore, we propose an adapted **EA** to achieve **that multi-model selection** by defining specific **fitness** function and **recombination operator**.

BACKGROUND

The multi-class classification problem refers to assigning a class to a feature vector in a set of possible ones. Among all the possible inducers, Support Vector Machine (SVM) have particular high generalization abilities (Vapnik, 1998) and have become very popular in the last few years. However, **SVM** are binary classifiers and several **combination schemes** were developed to extend **SVM** for problems with more two classes (Rifkin & Klautau, 2005). These schemes are based on different principles: probabilities (Price, Knerr, Personnaz & Dreyfus, 1994), error correcting codes (Dietterich, & Bakiri, 1995), correcting classifiers (Moreira, & Mayoraz, 1998) and evidence theory (Quost, Denoeux & Masson, 2006). All these **combination schemes** involve the following three steps: 1) decomposition of a multi-class problem into several binary sub-problems, 2) **SVM** training on all sub-problems to produce the corresponding binary decision functions and 3) **decoding strategy** to take a final decision from all binary decisions. Difficulties rely on the choice of the **combination scheme** (Duan & Keerthi, 2005) and how to optimize it (Lebrun, Charrier, Lezoray & Cardot, 2005).

In this paper, we focus on step 2) when steps 1) and 3) are fixed. For that step, each binary problem needs to properly tune the SVM hyper-parameters (model) in

order to have a global low multi-class error rate with the combination of all binary decision functions involved in. The search for efficient values of hyper-parameters is commonly designed by the term of *model selection*. The classical way to achieve optimization of multi-class schemes is an individual model selection for each related binary sub-problem. This methodology overtones that a multi-class scheme based on SVM combination is optimal when each binary classifier involved in that **combination scheme** is optimal on the dedicated binary problem. But, if it is supposed that a **decoding strategy** can more or less easily correct binary classifiers errors, then individual binary model selection on each binary sub-problem cannot take into account error correcting possibilities. For this main reason, we are thinking that another way to achieve optimization of multi-class schemes is a global **multi-model selection** for binary problems altogether. In fact, the goal is to have a minimum of errors on a multi-class problem. The selection of all sub-problem models (multi-model selection) has to be globally performed to achieve that goal, even if that means that error rates are not optimal on all binary sub-problems when they are observed individually. EA is an efficient meta-heuristic approach to realize that **multi-model selection**.

EA MULTI-MODEL SELECTION

This section is decomposed in 3 subsections. In the first section, the multi-model optimization problem for multi-class **combination schemes** is exposed. More details than in previous section and useful notations for next subsections are introduced. In the second section, our EA multi-model selection is exposed. Details on fitness estimation of multi-model and crossover operator over them are described. In the third section, experimental protocol and results with our EA multi-model selection are provided.

Multi-Model Optimization Problem

A multi-class combination scheme induces several binary sub-problems. The number k and the nature of binary sub-problems depend on the decomposition involved in the combination scheme. For each binary sub-problem, a **SVM** must be trained to produce an appropriate binary decision function h_i ($1 < i < k$). The quality of h_i is greatly dependent on the selected model

θ_i and is characterized by the expected error rate e_i for new datasets with the same binary decomposition. Each model θ_i contains all hyper-parameters values for training a SVM on dedicated binary sub-problem. Expected error rate e_i associated to a model θ_i is commonly determined by cross-validation techniques. All the θ_i models constitute the multi-model $\theta = (\theta_1, \dots, \theta_k)$. The expected error rate e of a SVM multi-class combination scheme is directly dependent on the selected multi-model θ . Let Θ denote the multi-model space for a multi-class problem (*i.e.* $\forall \theta : \theta \in \Theta$) and Θ_i the model space for the i^{th} binary sub-problem. The best θ^* multi-model is the one for which expected error e is minimum and corresponds to the following optimization problem:

$$\theta^* = \arg \min_{\theta \in \Theta} e(\theta) \quad (1)$$

where $e(\theta)$ denotes the expected error e of a multi-class combination scheme with the multi-model θ . The huge size of the multi-model space ($\Theta = \times_{i \in [1, k]} \Theta_i$) makes the optimization problem (0.1) very hard. To reduce the optimization problem complexity, it is classic to use the following approximation:

$$\tilde{\theta} = \{ \arg \min_{\theta \in \Theta} e(\theta_i) \mid i \in [1, k] \} \quad (2)$$

Hypothesis is made that

$$e(\tilde{\theta}) \approx e(\theta^*).$$

This hypothesis also supposes that

$$e(\tilde{\theta}_i) \approx e(\theta_i^*).$$

If it is evident that each individual model θ_i in the best multi-model θ^* must correspond to efficient **SVM** (*i.e.* low value of e_i) on the corresponding i^{th} binary sub-problem, all best individual models ($\theta_1^*, \dots, \theta_k^*$) do not necessarily define the best multi-model θ^* . The first reason is that all error rates e_i are estimated with some tolerance and combination of all these deviations can have a great impact on the final multi-class error rate e . The second reason is that even if all the binary classifiers of a **combination scheme** have identical e_i error rates for different multi-models, these binary classifiers can have different binary class predictions for a same

example according to the used multi-model. Indeed multi-class predictions by combining these binary classifiers could be different for a same feature vector example since the correction involved in a given **decoding strategy** depends on the nature of the internal errors of the binary classifiers (mainly, the number of errors). Then, multi-class classification schemes with the same internal-errors e_i , but different multi-models θ , can have different capacities of generalization. For all these reasons, we claim that multi-model optimization problem (0.1) can outperform individual model optimization (0.2).

Evolutionary Optimization Method

Within our AE multi-model selection method, a **fitness** measure f is associated to a multi-model θ which is all the more large as the error e associated to θ is small; this enables to solve (0.1) optimization problem. **Fitness** value is normalized in order to have $f=1$ when error e is zero and $f=0$ when error e corresponds to a random draw. Moreover, the number of examples in each class are not always well balanced for many multi-class datasets; to overcome this, the error e corresponds to a Balanced Error Rate (**BER**). As regards these two key points, the proposed fitness formulation is:

$$f = \frac{1}{1 - \frac{1}{n_c}} \left(1 - \frac{1}{n_c} - e \right) \quad (3)$$

with n_c denoting the number of classes in a multi-class problem. In the same way, the internal-fitness f_i is defined as $f_i = 1 - 2e_i$ for the i^{th} binary classifier with corresponding **BER** e_i .

The EA **crossover operator** for the combination of two multi-models θ^1 and θ^2 must favor the selection of most efficient models in these two multi-models. It is worth noting that one should not systematically select all the best models to produce an efficiency child multi-model θ as explained in previous sub-section. For each sub-problem, internal-fitness f_i^1 and f_i^2 are used to determine the probability

$$p_i = \frac{(f_i^1)^2}{(f_i^1)^2 + (f_i^2)^2} \quad (4)$$

to select the i^{th} model in θ^1 as the i^{th} model in the child multi-model θ . f_i^j denotes the internal fitness of the i^{th} binary classifier with the multi-model θ^j . For the child multi-models generated by the **crossover operator**, an important advantage is that no new SVM training is necessary if all the related binary classifiers were already trained. In contrast, only the **BER** error rates of all child multi-models have to be evaluated. **SVM Training** is only necessary for the first step of the **EA** and when models go through a mutation operator.

The rest of our **EA** for **multi-model selection** is similar to other **EA** approaches. First, at initialization step, a population of λ multi-models is generated at random. Each model θ_i^j ($1 \leq i \leq \lambda$, $1 \leq j \leq k$) corresponds to an uniform random within all possible values of SVM hyper-parameters. New multi-models are produced by combination of multi-models couples selected by a Stochastic Universal Sampling (**SUS**) strategy. A fixed selective pressure p_s is used for the **SUS** selection. Each model θ_i^j has a probability of p_m/k to mutate (uniform random as for the initialization step of EA). **Fitness** f of all child multi-models are then evaluated. A second selection step is used to define the population of the next iteration of our **EA**. λ individuals are selected by a **SUS** strategy (same selective pressure p_s is used) from both the λ parents and the λ children. Its become the multi-models population in the next iteration. The number of iterations of **EA** is fixed to n_{\max} . At the end of the **EA**, the multi-model with the best **fitness** f from all these iterations is selected as θ^* .

Experimental Results

In this section, three well known multi-class datasets are used: Satimage ($n_c = 6$), Letter ($n_c = 26$) from the Statlog collection (Blacke & Merz, 1998), and USPS ($n_c = 10$) dataset (Vapnik, 1998). In (Wu, Lin & Weng, 2004), two sampling sizes of 300/500 and 800/1000 are used to constitute training/testing datasets. For each sampling sizes, 20 random splits are generated. We have used the same sampling sizes and the same split for the 3 datasets: Satimage, Letter and USPS. Two optimization methods are used for the selection of the best multi-model θ^* for each training datasets. The first one is the classical individual model selection and the second one is our **EA multi-model selection**. For both methods, two combination schemes are used:

Table 1. Average BER with individual model selection (column \bar{e}_{classic}) and our EA multi-model selection (column \bar{e}_{EA}). Negative values in column $\Delta\bar{e}(\Delta\bar{e} = \bar{e}_{\text{EA}} - \bar{e}_{\text{classic}})$ correspond to an improvement of the performance of a multi-class combination scheme when our EA multi-model selection method is used.

| Size | 500 | | | 1000 | | |
|-----------------------|----------------------------|-----------------------|-----------------|----------------------------|-----------------------|-----------------|
| | \bar{e}_{classic} | \bar{e}_{EA} | $\Delta\bar{e}$ | \bar{e}_{classic} | \bar{e}_{EA} | $\Delta\bar{e}$ |
| <i>one-versus-one</i> | | | | | | |
| Satimage | 14.7 ± 1.8 % | 14.5 ± 2.1 % | -0.2 % | 11.8 ± 0.9 % | 11.8 ± 1.0 % | -0.0 % |
| USPS | 12.8 ± 1.2 % | 11.0 ± 1.8 % | -1.8 % | 8.9 ± 0.9 % | 8.4 ± 1.6 % | -0.5 % |
| Letter | 40.5 ± 3.0 % | 35.9 ± 2.9 % | -4.6 % | 21.4 ± 1.7 % | 18.6 ± 2.1 % | -2.8 % |
| <i>one-versus-all</i> | | | | | | |
| Satimage | 14.6 ± 1.7 % | 14.5 ± 2.0 % | -0.1 % | 11.5 ± 0.8 % | 11.6 ± 1.0 % | +0.1 % |
| USPS | 11.9 ± 1.3 % | 11.2 ± 1.5 % | -0.7 % | 8.8 ± 1.3 % | 8.5 ± 1.6 % | -0.3 % |
| Letter | 41.9 ± 3.3 % | 36.3 ± 3.3 % | -5.6 % | 22.1 ± 1.3 % | 19.7 ± 1.8 % | -2.4 % |

one-versus-one and *one-versus-all* (Rifkin & Klautau, 2004)¹. For each binary problem, a SVM with Gaussian kernel $K(u,v) = \exp(-\gamma\|u - v\|^2)$ is trained (Vapnik, 1998). Possible values of SVM hyper-parameters for a model are C trade-off SVM constant (Vapnik, 1998) and widthband γ of gaussian kernel function ($\theta_i \equiv (C_i, \gamma_i)$). For all binary problems: $\theta_i \in \Theta_i = [2^{-5}, 2^{-3}, \dots, 2^{15}] \times [2^{-5}, 2^{-3}, \dots, 2^{15}]$. Individual space model Θ_i is based on grid search techniques (Chang & Lin, 2001). **BER** e on a multi-class problem and **BER** e_i on binary sub-problems are estimated by five-fold **cross-validation** (CV). These **BER** values are used by our **EA** for the **multi-model selection**. Final **BER** e of a selected multi-model by our **EA** is estimated on a test datasets not used during the **multi-model selection** process. Our EA has several constants that must be fixed and we have made the following choices: $p_s = 2$, $\lambda = 50$, $n_{\max} = 100$, $p_m = 0.01$.

Table 1 gives average **BER** under all 20 split sets of previously mentioned datasets for each training set size (row size of table 1). This is done for the two combination schemes (*one-versus-one* and *one-versus-all*), and for the two above mentioned selection methods (columns \bar{e}_{classic} and \bar{e}_{EA}). Column $\Delta\bar{e}$ provides the average variation of **BER** between our **multi-model selection** and classical one. Results of that column are particularly important. For two datasets (USPS and Letter) our

optimization method produces SVM **combination schemes** with best **generalization capacities** than the classical one. That effect appears to be more marked when number of classes in the multi-class problem increases. A reason is that the multi-model space search size exponentially increases with the number k of binary problems involved in a **combination scheme** (121^k for those experiments). This effect is directly linked to the number of classes n_c and could explain why improvements are not measurable with Satimage dataset. In some way, a classical optimization method explores the multi-model space Θ in blink mode, because cumulate effect of the combination of k SVM decision functions could not be determined without estimation of e . That effect is emphasized when estimated **BER** e_i are poor (*i.e.* training and testing data size are low). Comparison of $\Delta\bar{e}$ values when training/testing dataset size change in table 1 illustrates this one.

FUTURE TRENDS

The proposed **EA multi-model selection** method has to be tested with other **combination schemes** (Rifkin & Klautau, 2004), like error-correcting output codes in order to measure their influence. Effect with others datasets, which have a great range in number of classes,

must also be tested. Adding feature selection (Fröhlich, Chapelle & Schölkopf, 2004) abilities to our AE multi-model selection is also of importance.

Another key point to take into account is the reduction of the learning time of our EA method which is actually expensive. One way to explore this is to use fast CV error estimation technique (Lebrun, Charrier, Lezoray & Cardot, 2006) for the estimation of BER.

CONCLUSION

In this paper, a new **EA multi-model selection** method is proposed to optimize the generalization capacities of SVM **combination schemes**. The definition of a **cross-over** operator based on internal **fitness** of SVM on each binary problem is the core of our EA method. Experimental results show that our method increases the **generalization capacities** of *one-versus-one* and *one-versus-all* **combination schemes** when compared with individual model selection method.

KEY TERMS

Cross-Validation: A method of estimating predictive error of inducers. Cross-validation procedure splits

that dataset into k equal-sized pieces called folds. k predictive function are built, each tested on a distinct fold after being trained on the remaining folds.

Evolutionary Algorithm (EA): Meta-heuristic optimization approach inspired by natural evolution, which begins with potential solution models, then iteratively applies algorithms to find the fittest models from the set to serve as inputs to the next iteration, ultimately leading to a sub-optimal solution which is close to the optimal one.

Model Selection: Model Selection for Support Vector Machines concerns the tuning of SVM hyper-parameters as C trade-off constant and the kernel parameters.

Multi-Class Combination Scheme: A combination of several binary classifiers to solve a given multiclass problem.

Search Space: Set of all possible situations of the problem that we want to solve could ever be in.

Support Vector Machine (SVM): SVM maps input data in a higher dimensional feature space by using a non linear function and finds in that feature space the optimal separating hyperplane maximizing the margin (that is the distance between the hyperplane and the closest points of the training set) and minimizing the number of misclassified patterns.

Trade-Off Constant of SVM: The trade-off constant, noted C , permit to fix the importance to increase the margin for the selection of optimal hyper-plan in comparison with reducing predictive errors (i.e. examples which not respect margin distance from hyper-plan separator).

ENDNOTE

INTRODUCTION

Throughout the last decades, one of society's concerns has been the development of new tools to optimize every aspect of daily life. One of the mechanisms that can be applied to this effect is what is nowadays called Artificial Intelligence (AI). This branch of science enables the design of intelligent systems, meaning that they display features that can be associated to human intelligence, search methods being one of the most remarkable. Amongst these, Evolutionary Computation (EC) stands out. This technique is based on the modeling of certain traits of nature, especially the capacity shown by living beings to adapt to their environment, using as a starting point Darwin's Theory of Evolution following the principle of natural selection (Darwin, 1859). These models search for solutions in an automatized way. As a result, a series of search techniques which solve problems in an automatized and parallel way has arisen. The most successful amongst these are Genetic Algorithms (GA) and, more recently, Genetic Programming (GP). The main difference between them is rooted on the way solutions are coded, which implies certain changes in their processing, even though the operation in both systems is similar.

Like most disciplines, the field of Civil Engineering is no stranger to optimization methods, which are applied especially to construction, maintenance or rehabilitation processes (Arciszewski and De Jong, 2001) (Shaw, Miles and Gray, 2003) (Kicing, Arciszewski and De Jong, 2005). For instance, in Structural Engineering in general and in Structural Concrete in particular, there are a number of problems which are solved simultaneously through theoretical studies, based on physical models, and experimental bench-

marks which sanction and adjust the former, where a large amount of factors intervene. In these cases, techniques based on Evolutionary Computation are capable of optimizing constructive processes while accounting for structural safety levels. In this way, for each particular case, the type of materials, their amount, their usage, etc. can be determined, leading to an optimal development of the structure and thus minimizing manufacturing costs (Rabuñal, Varela, Dorado, González and Martínez, 2005).

GENETIC ALGORITHMS

At the origin of what is now known as Genetic Algorithms are the works of John Holland at the end of the 1960's. He initially named them "Reproductive Genetic Planning", and it wasn't until the 70's that they received the name under which they are known today (Holland, 1975).

GA is a search algorithm inspired on the biological functioning of living beings. It is based upon reproductive processes and the principle which determines that better environmentally adapted individuals have more chances of surviving (Goldberg, 1989).

Like living beings, GAs use the basic heritage unit, the gene, to obtain a solution to a problem. The full set of genes (parameters characterizing the problem) is chromosome, and the expression of the chromosome is an individual in particular.

In Computer Science terms, the representation of each individual is a chain, usually binary, assigning a certain number of bits to each parameter. For each variable represented a conversion to discrete valued has to be performed. Obviously, not all parameters have

to be coded with the same number of bits. Each one of the bits in a gene is usually called allele. Once the individuals' genotype (the structure for the creation of an individual in particular) is defined, we are ready to carry out the evolutionary process that will reach the solution to the problem posed.

We start with a random set of individuals, called a population. Each of these individuals is a potential solution to the problem. This would be the initial population or zero generation, and successive generations will be created from it until the solution is reached. The mechanisms used in the individuals' evolution are analogous to the functioning of living beings:

- **Selection** of individuals for reproduction. All selection algorithms are based on the choice of individuals by giving higher survival probabilities to those which offer a better solution to the problem, but allowing worse individuals to be also selected so genetic diversity will not be lost. Unselected individuals will be copied through to the following generation.
- Once the individuals have been selected, **crossover** is performed. Typically, two individuals (parents) are crossed to produce two new ones. A position is established before which the bits will correspond to one parent, with the rest belonging to the other. This crossover is named single point crossover, but a number of points could be used, where bit subchains separated by points would belong alternatively to one or the other parent.
- Once the new individuals have been obtained, small variations in a low percentage of them are performed. This is called **mutation**, and its goal is to carry out an exploration in the state space.

Once the process is over, the new individuals will be inserted in the new population, constituting the next generation.

New generations will be produced until the population has created a sufficiently adequate solution, the maximum number of generations has been reached, or the population has converged and all individuals are equal.

GENETIC PROGRAMMING

Genetic Programming (GP), like GAs, is a search mechanism inspired on the functioning of living beings. The greater difference between both methods consists in the way solutions are coded. In this case, it is carried out as a tree structure (Koza, 1990) (Koza, 1992). The main goal of GP is to produce solutions to problems through program and algorithm induction.

The general functioning is similar to that of the GAs. Nevertheless, due to the difference in solution coding, great variations exist in the genetic operations of initial solution generation, crossover and mutation. The rest of operations, selection and replacement algorithms, remain the same, as do the metrics used to evaluate individuals (fitness).

We will now describe two cases where both techniques have been applied. They refer to questions related to Structural Concrete, approached to as both a material and a structure.

EXAMPLE 1: Procedure to determine optimal mixture proportion in High Performance Concrete.

High Performance Concrete (HPC) is a type of concrete designed to attain greater durability together with high resistance and good properties in its fresh state to allow ease of mixing, placing and curing (Forster, 1994) (Neville and Aitcin, 1998). Its basic components are the same of ordinary concrete, with the intervention in diverse quantities of additions (fly ash or silica fume, byproducts of other industries that display pozzolanic resistance capacities) plus air-entraining and/or fluidifying admixtures. Indeed, an adequate proportion of these components with quality cement, water and aggregates produces concrete with excellent behavior, generally after an experimental process to adjust the optimal content in each material. When very high resistance is not a requirement, the addition introduced is fly ash (FA); air-entraining admixtures (AE) are used to improve behavior in frost/defrost situations. When high resistance is needed, FA is substituted by a silica fume (SF) addition, eliminating AE altogether. In every case high cement contents and low water/binder (W/B) ratios are used (both cement and pozzolanic additions are considered binders).

A number of mixture proportioning methods exist, based on experimental approaches and developed by different authors. The product of such mixtures can

be controlled through various tests, two of which are particularly representative of the fresh and hardened states of concrete: the measurement of workability and evaluation of compressive strength, respectively. The first one is carried out through the slump test, where the subsidence of a molded specimen after removal of the mold is measured. A high value ensures adequate placing of concrete. The second test consists on the compression of hardened concrete until failure is produced; HPC can resist compressive stresses in the range of 40 to 120 MPa.

The goal of mixture proportioning methods is to adjust the amount of each component to obtain slump and strength values within a chosen range. There is a large body of experience, and basic mixtures which require some experimental adjustment are available. It is difficult to develop a theoretical model to predict slump and resistance of a particular specimen, though roughly adequate fitted curves do exist (Neville, 1981). It is even harder to approach theoretically the reverse problem, that is, to unveil mixture proportioning starting from the goal results (slump and strength).

Chul-Hyun Lim et al. (Chul-Hyun, Young-Soo and Joong-Hoon, 2004) have developed a GA based application to determine the relationship between different parameters used to characterize a HPC mixture. Two types of mixture are considered regarding their goal strength: mixtures that reach values between 40 and 80 MPa and mixtures that reach between 80 and 120 MPa. If a good database is available, it is not hard to obtain correlations between different variables to predict slump and strength values for a particular specimen. Nevertheless, the authors use GAs to solve the reverse problem, that is, to obtain mixture parameters when input data are slump and strength.

To that effect they use a database with 104 mixtures in the 40 to 80 MPa range and 77 in the 80 to 120 MPa range. In the first group, essential parameters are, according to prior knowledge, W/B ratio (%), amount of water (W , kg/m^3), fine aggregate to total aggregate ratio (s/a , %), amount of AE admixture (kg/m^3), amount of cement replaced by FA (%), and amount of high-range water-reducing admixture (superplasticizer, SP, kg/m^3). Tests on the different mixtures give slump values (between 0 and 300 mm) and compressive strength. In the second group, essential parameters are W/B, W , s/a , amount of cement replaced by silica fume (SF, %) and SP. Tests give out slump and resistance values.

Using multiple regression techniques, the authors firstly obtain for each group two fitted curves group that predict slump and strength from starting variables. GAs are used to solve the reverse problem. For each group, they first reach an individual which determines optimal W/B, W , s/a , FA and AE, or W/B, W , s/a and SF for a specific compressive strength. From these parameters, using the prediction curve previously obtained, the optimal SP value for a particular slump is calculated.

The development of genetic algorithms used is based on programs by Houck et al. (Houck, Joines, and Kay 1996) In this case, “ranking selection based on normalized geometric distribution” has been used for individual selection. One-point, two-point, and uniform crossover algorithms are used. Different strategies are used for mutation operations: boundary mutation, multi-nonuniform mutation, nonuniform mutation, and uniform mutation. The first trials were carried out with an initial population consisting of only 15 individuals, which lead to local minima only. Optimal results are obtained increasing population to 75 individuals.

It should be pointed out that the reverse problem is thus solved in two phases. In the first phase all component amounts are fixed except for SP, with compressive strength as a target; following this, SP is fixed to attain the desired slump. Initial fitting functions are used as a simple but accurate approach to the real database, to avoid using it directly, which would make solving the reverse problem a more difficult task.

For the first group, highest errors correspond to AE and SP determination, up to 12.5% and 15% respectively. Errors committed in the second group are smaller. In any case, errors are relatively minor since these materials are included as admixtures in very small amounts. As a conclusion for this example, it is interesting to point out that the procedure is not only a useful application of GAs to concrete mixture proportioning, but also constitutes by itself a new mixture proportioning method that requires GAs for its application.

EXAMPLE 2: Determination of shear strength in reinforced concrete deep beams

Deep beams are those that can be considered short (span, L) in relation to their depth (h). There is no consensus in international codes as to what is the span-to-depth threshold value dividing conventional and deep beams. In the example shown here, L/h ratios between 0.9 and

Figure 1. Deep beam parameters

4.14 are considered for simply supported elements working under two point loads as shown in Figure 1. Shear failure is a beam collapse mode produced by the generation of excessive shear stresses in the vicinity of the supports. Its value depends on various parameters commonly used for beam design (see Figure 1): a/h , L/h , section area (A_{sv} and A_{sh}), strength (f_{yv} and f_{yh}) and distances between vertical and horizontal steel rebars (s_v y s_h) placed in the failure zone, which will be respectively called vertical and horizontal transverse reinforcement; section area (A_{sb} and A_{st}) and strength (f_{yb} and f_{yt}) of longitudinal rebars placed in the lower and higher zones of the beam, which will be respectively called bottom and top reinforcement; compressive strength of concrete used in the beam, and width (b) of the latter.

The dependence of shear strength on these parameters is known through multiple studies (Leonhardt and Walther, 1970) and it can be presented in a normalized form through simple relationships. Relevant parameters are reduced to the following:

- $X_1 = a/h$
- $X_2 = L/h$
- $X_3 = (A_{sv} f_{yv}) / (b s_v f_c)$
- $X_4 = (A_{sh} f_{yh}) / (b s_h f_c)$
- $X_5 = (A_{sb} f_{yb}) / (b h f_c)$
- $X_6 = (A_{st} f_{yt}) / (b h f_c)$

Normalized shear strength can be written as $R = P / (b h f_c)$, where P is failure load (Figure 1).

Ashour et al. (Ashour, Alvarez and Toropov, 2003) undertake the task of finding an expression that can predict shear strength from these variables. It is not easy to develop an accurate mathematical model capable of predicting shear strength. Usual curve fitting techniques do not produce good results either, though they have been the base of diverse international codes that include design prescriptions for these structural elements. GP appears to be a tool that can reach consistent results. The authors develop various expressions with different complexity levels, obtaining different degrees of accuracy. A database of 141 tests available in scientific literature is used.

A remarkable feature of GP techniques is that if the possibility of using complex operators is introduced, fitting capacity is impressive when variables are well distributed and their range is wide. Notwithstanding, if the goal of the process is to obtain an expression that can be used by engineers, one of its requirements is simplicity. The authors of this study take into account this premise and only choose as operators addition, multiplication, division and squaring. A first application leads to a complex expression that reveals the very low influence of parameter X_2 , which is thus eliminated. With the 5 remaining variables, a simple and accurate expression is obtained (root mean square –RMS– training error equal to 0.033; average ratio between predicted and real R equal to 1.008 and standard deviation equal

to 0.23). Validation of this expression is performed with 15 new tests and also found to be accurate: RMS error equal to 0.035; average ratio between predicted and real R values equal to 1.11 and standard deviation equal to 0.21.

As a conclusion to this example, it can be pointed out that expressions obtained through GP bring as an added value that they can become virtual laboratories. Indeed, by fixing one or multiple variables, the influence on the response of the variation of a specific one, and also determine which variables are most important in the studied phenomenon (in this case, X_1 and X_5). Finally, GP techniques prove to be a powerful tool for the development and improvement of codes that regulate concrete structure design. Even when the precise physical mechanism is unknown, GP allows for the development of accurate expressions that can be factored a posteriori to reach safety levels associated to an acceptable failure probability.

CONCLUSION

Evolutionary Computation is a valid technique for optimization and regression problems in the fields of Structural Engineering in general and Structural Concrete in particular.

In the first of the two examples analyzed, GAs have been used to determine optimal mixture proportion for High Performance Concrete, using as target data its compressive strength and workability. In this case, evolutionary techniques show their power by solving the reverse problem, producing a new mixture proportioning method for concrete.

In the second example, GP techniques were used to accurately predict structural response of concrete beams from benchmark experimental data series. The advantage brought forth by Evolutionary Computation is the capacity to analyze physically complex phenomena, by creating a “virtual laboratory”. The line of work opened towards the improvement of design codes and rules sometimes purely based on testing is also of great importance.

Application of EC techniques is growing exponentially in this field thanks to fruitful collaboration between EC and Structural Engineering experts.

KEY TERMS

Compressive Strength: The measured maximum resistance of a concrete or mortar specimen to axial compressive loading; expressed as force per unit cross-sectional area; or the specified resistance used in design calculations.

Deep Beam: A flexural member whose span-to-depth ratio is too low to accurately apply the principles of sectional design through sectional properties and internal forces shear strength the maximum shearing stress a flexural member can support at a specific location as controlled by the combined effects of shear forces and bending moment

High Performance Concrete: Concrete meeting special combinations of performance and uniformity requirements that cannot always be achieved routinely using conventional constituents and normal mixing, placing, and curing practices.

Mixture Proportion: The proportions of ingredients that make the most economical use of available materials to produce mortar or concrete of the required properties.

Slump: A measure of consistency of freshly mixed concrete, mortar, or stucco equal to the subsidence measured to the nearest 1/4 in. (6 mm) of the molded specimen immediately after removal of the slump cone.

Superplasticizer or High-Range Water-Reducing Admixture: A water-reducing admixture capable of producing large water reduction or great flowability without causing undue set retardation or entrainment of air in mortar or concrete.

Workability: That property of freshly mixed concrete or mortar that determines the ease with which it can be mixed, placed, consolidated, and finished to a homogenous condition.

E-Learning in New Technologies

INTRODUCTION

E-learning and the impact of new technologies across contemporary life is a very significant field to education. The challenge of the technology to conventional learning patterns cannot be ignored and in itself raises a host of questions: can online learning facilitate deep learning? How well does video conferencing alleviate the challenge of distance? In what ways can collaborative learning communities be developed and sustained using current and new technologies? At the same time, new communications technologies are impacting on the ways in which we understand ourselves and the worlds in which we live. Relating to this, the aim of today's education is not to learn certain contents, but rather learn to learn in the course of a whole lifetime.

The study of the learning process can help us to find the relevant points to set up some interesting characteristics of a really functional e-learning system.

THE LEARNING PROCESS

The learning process consists of a modification of our conduct that, by extracting knowledge from acquired experience, enables us to tackle problems (Pedreira, 2004a). This definition highlights the two basic aspects of all learning processes: knowledge acquisition, and the experience that leads to it.

Most studies on the nature of knowledge agree on the fact that knowledge is at the top of the hierarchical structure called information. According to this vision, data represent facts or concepts in a formalised way that allows their communication, interpretation or elaboration by human beings or by automatic means (syntactic level of the information). The so-called “news” is the

meaning that an intelligent being attaches to data based on the conventional rules used for their representation (semantic level). Knowledge implies the judgement of facts and situations, and consists of inferred data and news, tacit relations between objects, concepts, events and situations, and of the necessary control actions to manage all these elements in an effective way. As such, knowledge concerns the pragmatic aspect of information because it combines the received news with the knowledge that the observer already possesses.

EDUCATION IN KNOWLEDGE SOCIETY

In recent years, so many changes have affected education that education itself needs to be updated. The amount of knowledge that we deal with is much bigger than before, the interrelations between different forms of information are much more complex, and the sources are dispersed. Such being the case, the linear model, in which each question has a place and a moment, is no longer adequate for today's information. Logical hierarchies are replaced by multiple and simultaneous media that respond to the needs of the knowledge process. The inevitable increase in complexity and quantity of the information that is available and necessary has led to a need for continuous learning.

Furthermore, in modern society, knowledge is not exclusively related to education. We live in what is called the “information or knowledge society”, where the possession of knowledge is a determining factor.

Knowledge handling requires a profound transformation of learning and teaching methods: from a model in which the teacher is the monopolising agent and the authorised representative of knowledge, we must move towards a model that offers the student room for

individual exploration and self-learning. The student needs to build relations, discover the process from within, and feel stimulated to draw his own roadmap (Piaget, 1999).

This kind of learning can only be obtained through action strategies that are not perceived as restricting obligations but rather as interesting learning options. Contents, for instance, should be represented not as an object of study but rather as necessary elements towards a series of objectives that will be discovered in the course of various tests. Computer games apply the same strategy by making their users learn to proceed from one phase to another based on obtained experience and improved dexterity. This way they keep users entertained for hours in a row by trial and error.

Besides, students come from different environments and have different ages and education backgrounds, which make it more complicated to integrate them into one single group. Real personalised attention would require many more teachers and much more time. Add to that the increasing demand for continuous education, with flexible timetables and subjects, and it becomes clear that the current programmes are much too rigid.

The advantages of e-learning include convenience and portability (physical and temporal flexibility), cost and selection (wide range of courses and prices, different levels), individualisation and a higher level of student implication (WorldWideLearn, 2007).

However, if the contents of the learning platforms remain the same as those of traditional systems, even if their presentation format is adapted, they do not substantially contribute to the improvement of the learning process (Martínez, 2002). The same happens with the use of computational systems that support ex cathedra teaching and improve the acquisition of certain skills, such as simulators and games. Simulators can only be used when certain concepts are already clearly understood, and in most cases, their interface is quite complicated. Computer games are mostly used for concrete aspects and in elementary courses.

Instructional Design for e-Learning has been perfected and refined over many years using established teaching principles, with many benefits to students, but it is necessary to go on with the studies on this area because the results are still not as good as desired.

NEW TECHNOLOGIES PROPOSAL

Even so, current communication technologies, including Artificial Intelligence, allow the implementation of learning strategies based on action (e.g. videogames), the incorporation of systems that improve knowledge management (Wiig, 1995), the recuperation of the one-to-one learning model (master-apprentice becomes teacher-student), and the implementation of a new learning model ("many teachers for one student"). A computer model including all these characteristics can be a solid basis for the improvement of the learning process and the existing e-learning systems. It could teach the students more than just certain contents: it could teach them how to learn, by selecting and sharing the adequate information in each moment.

In this point, we will remark some pedagogical characteristics of e-learning computer models which are known to improve the learning process. For each of these characteristics we propose a feature that can be implemented by using New Technologies.

Pedagogical Characteristic 1

Dealing with *information of different sources* will allow the students seeing different points of view of the same realities, making easy its understanding and its conservation in mind.

New Technologies Feature 1

In the Institutional Memory of a *Knowledge Management System*, we will find all the information concerning every thematic unit, different levels and its associated tasks. The fact of being able to solve different tasks and having the access into information of different sources allows the learner to acquire the information by different means, so that his knowledge will be more complete and everlasting.

Pedagogical Characteristic 2

An e-learning model should provide an *individual attention*, taking into account the student's preferences about learning strategies, different kind of materials, their previous knowledge, etc.

New Technologies Feature 2

In order to get it, some *intelligent agents* can take charge of selecting and showing, in any case, the suitable information (from the information repository) according to the preferences and level of each student. These agents can perform different tasks, and divide them between the users' computers and the server where the Institutional Memory is stored.

Pedagogical Characteristic 3

An e-learning model must *facilitate the students all the available information*, in different formats and coming from different sources, for the students to learn how to choose the most relevant elements for their learning.

New Technologies Feature 3

To reach this, it can be used a *global ontology*, establishing a classification in levels and the relationships between the available information, managed through the Knowledge Management System.

Pedagogical Characteristic 4

Computer e-learning models ought to *propose this apprenticeship by means of works and problems to solve*, so that the students knowledge grows as they go on with the resolution of their works.

New Technologies Feature 4

It is necessary to establish much different kind of works, at different levels, for each unit the student must prepare. The tasks and the available information as well, will be founded in the Institutional Memory organized under *ontology*, making easy the access to the relevant information at any moment. Carrying out the tasks, the learner will build his own knowledge (Nonaka, 1995).

Pedagogical Characteristic 5

An e-learning model should join *strategies to get and raise the student's motivation* and encourage its inquisitiveness, relating the available information with its interest, proposing the possibility of explore deeper

the same or related subjects and using the computer games strategies that give rise to investigate.

New Technologies Feature 5

When the contents of the course are part of an Institutional Memory, the existence of a global ontology can facilitate the display of the elements remarking the connections between them. Besides, as alleged previously, the use of intelligent agents allows us to show these connections according to the individual preferences. The *strategies utilized in computer games, including the apprenticeship through the action* will help to attract and maintain the student's interest.

FUTURE WORKS

Some prototypes for the aspects mentioned in the previous point have been developed in our research laboratory for testing the proposed features (Pedreira, 2004a, 2004b, 2005a, 2005b). Each of them has reached quite good results. These approximations show that the use of New Technologies on education allows the students to extend or improve their problem-solving methods and their abilities to transfer knowledge (Friss de Kereki, 2004). After these first approaches, we are working on the joint of the prototypes and their enlargement with some characteristics that have not still been tested.

CONCLUSION

In this article we suggest several features that e-learning systems should have in order to improve online learning, which can be achieved by using New Technologies. In short, we propose a computer model based on a Knowledge Management System which, by using a global ontology, maintains the highest quantity of relationships between the available information and its classification at different levels. By means of this support of knowledge, apprenticeship can be established by means of task proposal, based on computer game strategies. Using the philosophy of intelligent agents, these systems can interact with the students showing them the information according to their preferences, in order to motivate them and to stimulate their capacity of raising questions.

KEY TERMS

Best Practice: A management idea which asserts that there is a technique, method, process, activity, incentive or reward that is more effective at delivering a particular outcome than any other technique, method or process.

Computer Game: A video game played on a personal computer, rather than on a video game console or arcade machine.

Computer Model: A computer program that attempts to simulate an abstract model of a particular system.

E-Learning: Learning that is accomplished over the Internet, a computer network, via CD-ROM, interactive TV, or satellite broadcast

Intelligent Agent: A real time software system that interacts with its environment to perform non-repetitive computer-related tasks.

Knowledge Management: The collection, organization, analysis, and sharing of information held by workers and groups within an organization.

Learn to Learn: In this context, learn to manage (select, extract, classify) the great amount of information existing in actual society, in order to identify real and significant knowledge.

New Technologies: In this context, Computer, Information and Communication Technologies.

Virtual: Not physical.

Emerging Applications in Immersive Technologies

Darryl N. Davis

University of Hull, UK

Paul M. Chapman

University of Hull, UK

INTRODUCTION

The world of Virtual Environments and Immersive Technologies (Sutherland, 1965) (Kalawsky, 1993) are evolving quite rapidly. As the range and complexity of applications increases, so does the requirement for intelligent interaction. The now relatively simple environments of the OZ project (Bates, Loyall & Reilly, 1992) have been superseded by Virtual Theatres (Doyle & Hayes-Roth, 1997) (Giannachi, 2004), Tactical Combat Air (Jones, Tambe, Laird & Rosenbloom, 1993) training prototypes and Air Flight Control Simulators (Wangermann & Stengel, 1998).

This article presents a brief summary of present and future technologies and emerging applications that require the use of AI expertise in the area of immersive technologies and virtual environments. The applications are placed within a context of prior research projects.

BACKGROUND

Visualisation is defined as the use of computer-based, interactive visual representations of data to amplify cognition. The much cited process driven visualisation pipeline proposed by Upson et al (1989) is shown in Figure 1. Upson and his colleagues define three processes consisting of filtering, mapping and rendering the data. The image presented allows the user to draw some inference and gain insight into the data.

The *Filter* process is when data of interest are derived from the raw input data; for example, an interpolation of scattered data onto a regular grid. This data is then *Mapped* into geometric primitives that can be then be *Rendered* and displayed as an image to the user. The user may then gain an improved understanding and greater insight into the original raw data. The type of data and application area heavily influence the nature of the mapping process. That is, choosing the actual visualisation technique that we are going to use. For example, if the data consisted of 1D scalar data, then a simple line graph can be used to represent the data. If the filtered data consists of 3D scalar data, then some form of 3D isosurfaces or direct volume rendering technique would be more appropriate. Through the various specifications and conceptualisations of the filter-map pipeline above, we would propose an ontology that describes the relationships between data type and mapping processes that facilitates the automatic selection of visualisation techniques based on the raw data type. As the applications become more sophisticated the visualisation process can make use of the data ontology to drive AI controlled characters and agents appropriate for the application and data.

A starting place for this can be seen in the area of believable agents (Bates, Loyall & Reilly, 1992) where the research ranges from animation issues to models of emotion and cognition, annotated environments. Innovative learning environments and Animated Pedagogical Agents (Johnson, Rickel & Lester, 2000) provide further areas for development, as do industrial

Figure 1. Upson et al's visualisation pipeline

applications, for example Computer Numerical Control (CNC) milling operations virtual training prototype system (Lina, Yeb, Duffy & Suc, 2002). Teaching environments using multiple interface devices in virtual reality include Steve (Soar Training Expert for Virtual Environments) that supports the learning process (Rickel & Johnson, 1999) with collaborators including Lockheed Martin AI Center. SOAR (Laird, Hucka & Huffman, 1991) has also been used for training simulation in air combat (TacAir-Soar) (Jones, Tambe, Laird & Rosenbloom, 1993). This autonomous system for modelling the tactical air domain brings together areas of AI research covering cognitive architectures Human Behavior Representation (HBR)/Computer Generated Forces (CGF). SOF-Soar: (Special Operations Forces Modeling) (Tambe, Johnson, Jones, Koss, Laird, Rosenbloom and Schwamb, 1995) uses the same underlying framework and methods for behavior generation based on the Soar model of human cognition, each entity is capable of autonomous, goal-directed decision-making, planning, and reactive, real-time behavior. As the world of digital media expands emerging applications will draw on the worlds of Virtual Theatres (Giannachi, 2004), interactive storyline games and others forms of entertainment (Wardrip-Fruin & Harrigan, 2004) to enhance the visualisation experience, especially where virtual worlds involving human artifacts and past and current civilisations are involved.

SWARM INTELLIGENCE FOR VISUALISATION

Understanding the behaviour of biological agents in their natural environment is of great importance to ethologists and biologists. Where these creatures move in large numbers is a challenge for orthodox visualisation.

Working with marine biologists, a 3D model of large numbers of swarming krill (Figure 2) has been created. The model augments the classic swarming functions of separation, alignment and cohesion outlined by Reynolds (1987). The generated 3D model allows cameras to be placed on individual krill in order to generate an in-swarm perspective. New research on Antarctic krill (Tarling & Johnson, 2006) reveals that they absorb and transfer more carbon from the Earth's surface than was previously understood. Scientists from the British Antarctic Survey (BAS) and Scarborough Centre of Coastal Studies at the University of Hull discovered that rather than doing so once per 24 hours, Antarctic krill 'parachute' from the ocean surface to deeper layers several times during the night. In the process they inject more carbon into the deep sea when they excrete their waste than had previously been understood. Our objective has been to provide marine biologists with a visualisation and statistical tool that permits them to change a number of parameters within the krill marine environment and examine the effects of those changes over time. The software can also be used as a teaching tool for the classroom at varying academic levels.

Figure 2. 3D krill and sample 3D swarm

The marine biologist may modify parameters relating to an individual krill's field of view, foraging speed, collision avoidance, exhaustion speed, desire for food etc. The researcher may also modify more global parameters relating to sea currents, temperature and quantity and density of algae (food) etc.

Upon execution, the biologist may interact with the model by changing the 3D viewpoint and modifying the time-step which controls the run speed of the model. Krill states are represented using different colours. For example, a red krill represents a starved unhealthy krill, green means active and healthy, blue represents a digestion period where krill activity is at a minimal. Recent advances in processor and graphics technology means that these sorts of simulations are possible using high specification desktop computers. Marine biologists have been very interested in seeing how making minor changes to certain variables, such as field of view for krill, can have major consequences to the flocking behaviour over time of the entire swarm.

PARAGLIDING SIMULATOR

The Department of Computer Science at the University of Hull have recently developed the world's first ever paragliding simulator (SimVis, 2007). The system provides a paragliding pilot with a virtual reality immersive flying experience (Figure 3). As far as the user is concerned, they are flying a real paraglider. They sit in a real harness and all physical user inputs are the same as real life. Visuals are controlled via a computer and displayed to the user via a head-tracked helmet mounted display. The simulator accurately models winds (including thermals and updrafts), photorealistic terrain and other computer controlled AI pilots.

Figure 4 shows a typical view from the paragliding simulator. To the right of the image, the user can see four paragliding pilots circling a thermal. It is in the user's interests to fly to this region to share in the uplift, gaining altitude and therefore flight time.

This prototype is being developed along the lines of SOF-Soar: (Special Operations Forces Modeling) (Tambe, Johnson, Jones, Koss, Laird, Rosenbloom and Schwamb, 1995). It requires an expert tutoring system encompassing the knowledge of expert pilots. Like some virtual learning environments it needs to build a trainee profile from a default and adapt to the needs

Figure 3. VR paragliding simulator

of the novice flyer. For example the system can create an AI Pilot flying directly at the user forcing the user to practise collision avoidance rules. If pilots collide in the simulator, both pilots will become wrapped in each others canopies and they will plummet down to the earth and die. As virtual fly-time accumulates the system needs to adapt to the changing profile of the user. An expert system could be used to force the user to make certain flight manoeuvres that test the user's knowledge of CAA air laws. For example, the AI system may decide that the user is an advanced pilot due to their excellent use of thermal updrafts etc. The system therefore works out how to put our pilot into a compromising situation that would test their skills and ability such as plotting a collision course with our pilot when they are flying alongside a cliff edge. If our pilot is a novice, then the system would present simpler challenges such as basic collision avoidance. This is an advanced knowledge engineering project that blends traditional AI areas such as knowledge engineering with more nouvelle fields such as agent based reactive and cognitive architectures and state of the art visualisation and immersive technologies.

Figure 4. Real-time pilot's view from the paragliding simulator including other AI controlled pilots

CONCLUSION

This article suggests that cognitive science and artificial intelligence have a major role to play in emerging interface devices that require believable agents. As virtual environments and immersive technologies become ever more sophisticated, the capabilities of the interacting components will need to become smarter, making use of artificial-life, artificial intelligence and cognitive science. This will include the simulation of human behaviour in interactive worlds whether in the modelling of the way data and information is manipulated or in the use of hardware devices (such as the paraglider) within a virtual environment.

KEY TERMS

Air Flight Control: A service provided by ground-based controllers who direct aircraft on the ground and in the air. A controller's primary task is to separate certain aircraft — to prevent them from coming too close to each other by use of lateral, vertical and longitudinal separation. Secondary tasks include ensuring orderly and expeditious flow of traffic and providing information to pilots, such as weather, navigation information and NOTAMs (Notices to Airmen)

Flocking: A computer model of coordinated animal motion such as bird flocks and fish schools. Typically based on three dimensional computational geometry of the sort normally used in computer animation or computer aided design.

Knowledge Engineering: Knowledge engineering is a field within artificial intelligence that develops knowledge-based systems. Such systems are computer programs that contain large amounts of knowledge, rules and reasoning mechanisms to provide solutions to real-world problems. A major form of knowledge-based system is an expert system, one designed to emulate the reasoning processes of an expert practitioner (i.e. one having performed in a professional role for very many years).

Virtual and Immersive Environments: Virtual environments coupled with immersive technologies provide the sensory experience of being in a computer generated, simulated space. They have potential uses in applications ranging from education and training to design and prototyping.

Virtual Theatres: The concept of "Virtual Theatre" is vague and there seems to be no commonly accepted definition of the term. It can be defined as a virtual world inhabited by autonomous agents that are acting and interacting in an independent way. These agents may follow a predetermined manuscript, or act completely on their own initiative.

INTRODUCTION

The use of speech in human-machine interaction is increasing as the computer interfaces are becoming more complex but also more useable. These interfaces make use of the information obtained from the user through the analysis of different modalities and show a specific answer by means of different media. The origin of the multimodal systems can be found in its precursor, the “Put-That-There” system (Bolt, 1980), an application operated by speech and gesture recognition.

The use of speech as one of these modalities to get orders from users and to provide some oral information makes the human-machine communication more natural. There is a growing number of applications that use speech-to-text conversion and animated characters with speech synthesis.

One way to improve the naturalness of these interfaces is the incorporation of the recognition of user's emotional states (Campbell, 2000). This point generally requires the creation of speech databases showing authentic emotional content allowing robust analysis. Cowie, Douglas-Cowie & Cox (2005) present some databases showing an increase in multimodal databases, and Ververidis & Kotropoulos (2006) describe 64 databases and their application. When creating this kind of databases the main arising problem is the naturalness of the locutions, which directly depends on the method used in the recordings, assuming that they must be controlled without interfering the authenticity

of the locutions. Campbell (2000) and Schröder (2004) propose four different sources for obtaining emotional speech, ordered from less control but more authenticity to more control but less authenticity: i) natural occurrences, ii) provocation of authentic emotions in laboratory conditions, iii) stimulated emotions by means of prepared texts, and iv) acted speech reading the same texts with different emotional states, usually performed by actors.

On the one hand, corpora designed to synthesize emotional speech are based on studies centred on the listener, following the distinction made by Schröder (2004), because they model the speech parameters in order to transmit a specific emotion. On the other hand, emotion recognition implies studies centred on the speaker, because they are related to the speaker emotional state and the parameters of the speech. The validation of a corpus used for synthesis involves both kinds of studies: the former since it will be used for synthesis and the latter since recognition is needed to evaluate its content. The best validation system is the selection of the valid utterances¹ of the corpus by human listeners. However, the big size of a corpus makes this process unaffordable.

BACKGROUND

Emotion recognition has been an interesting research field in human-machine interaction for long, as can be

observed in Cowie et al. (2001). Some studies have been carried out to observe the influence of emotion in speech signals like the work presented by Rodríguez et al. (1999), but more recently, due the increasing power of modern computers that allows the analysis of huge amount of data in relatively small time lapses, machine learning techniques have been used to recognise emotions automatically by using labelled expressive speech corpora. Most of these studies have been centred on few algorithms and little sets of parameters.

However, recent works have performed more exhaustive experiments testing different machine learning techniques and datasets, as the described by Oudeyer (2003). All this kind of studies had the goal of achieving the best possible recognition rate obtaining, in many cases, better results than those obtained in subjective tests ((Oudeyer, 2003), (Planet, Morán & Formiga, 2006), (Iriondo, Planet, Socoró & Alías, 2007)). Nevertheless, many differences can be found when analyzing the results obtained from objective and subjective classifications and, to our knowledge, there are not studies with the goal of emulating these subjective criteria before those carried out by Iriondo, Planet, Alías, Socoró & Martínez (2007).

VALIDATION OF AN EXPRESSIVE SPEECH CORPUS BY MAPPING SUBJECTIVE CRITERIA

The creation of a speech corpus with authentic emotional content is one of the most important challenges in the study of expressive speech. Once the corpus is recorded, a validation process is required to prune those utterances that show distinct emotion to their label. This article is based on the work exposed by Iriondo, Planet, Alías, Socoró & Martínez (2007) and presents the production of an expressive speech corpus in Spanish with the goal of being used in a synthesis system, validating it by pruning automatically “bad” utterances emulating the criteria of human listeners.

The Production of the Corpus

The recording of the corpus has been carried out by a female professional speaker. There is a high consensus in the scientific community for obtaining emotional

speech by means of this strategy for synthesis purposes (Cowie et al., 2005), although other authors argue in favor of constructing enormous corpora gathered from recordings of the daily life (Campbell, 2005). For the design of texts semantically related to different expressive styles, we have made use of an existing textual database of advertisements extracted from newspapers and magazines. Based on a study of the voice in the audio-visual publicity (Montoya, 1998), five categories of the textual corpus have been chosen and the most suitable emotion/style has been assigned to them: New technologies (neutral-mature), education (joy-elation), cosmetic (style sensual-sweet), automobiles (aggressive-hard) and trips (sad-melancholic). The recorded database has 4638 sentences and it is 5 hours 12 minutes long.

From these categories, a set of sentences has been chosen by means of a greedy algorithm (François & Boëffard, 2002) that has allowed us to select phonetically balanced sentences. In addition to looking for a phonetic balance, phrases that contain foreign words and abbreviations have been discarded because they difficult the automatic process of phonetic transcription and labeling.

The corpus has been segmented in phrases and then in phonemes by means of a semiautomatic process based on a forced alignment with Hidden Markov Models.

Acoustic Analysis

Cowie et al. (2001) show how prosodic features of speech (fundamental frequency (F0), energy, duration of phones, and frequency of pauses) are related to vocal expression of emotion. The analysis of F0 performed in this work is based on the result of the pitch marks algorithm described by Alías, Monzo & Socoró (2006). This system can assign marks over the whole signal, interpolating values from the neighbour phonemes in unvoiced segments and silences. Energy is measured with 20 ms rectangular windows and 50% of overlap, computing the mean energy in decibels (dB) every 10 ms. Also, rhythm parameters have been incorporated using the z-score as a means to analyze the temporal structure of speech (Schweitzer & Möbius, 2003). Moreover, for each utterance two parameters relating the number of pauses per time unit and the percentage of silence respect to the total time are considered.

Subjective Test

A subjective test allows validating the expressiveness of a corpus of acted speech from a user's point of view. Nevertheless, an extensive evaluation of the complete corpus would be very tedious due the big amount of elements in it. For this reason, only a 10 percent of the corpus utterances have been selected for this test. A forced answer test has been designed using the TRUE platform (Planet, Iriondo, Martínez, & Montero, 2008) with the question: *What emotional state do you recognize from the voice of the speaker in this phrase?* The possible answers are the 5 emotional styles of the corpus and one more option *Don't know / Another* (Dk/A) in order to minimize biasing the results due to confusing cases. The addition of this option has the risk of allowing some users to use excessively this answer to accelerate the end of the test (Navas, Hernáez & Luengo, 2006). However, this effect has not been observed in this experiment. The evaluators were 30 volunteers with a quite heterogeneous profile.

The achieved average classification accuracy in the subjective test is 87%. The test also reveals that sad style (SAD) is the best rated (98.5% in average). The second and third best rated styles are sensual (SEN) (87.2%) and neutral (NEU) (86.1%), followed by happy (HAP) (81.9%) and aggressive (AGR) (81.6%). Aggressive and happy styles are often confused between them. Moreover, sensual is slightly misclassified as sad or neutral. The Dk/A option is hardly used, although it is more present in neutral and sensual than in the rest of styles.

To decide if utterances are not optimally performed by the speaker, two simple rules have been created from the subjective test results by empirically adjusting two thresholds. These rules remove utterances whose identification percentage is lower than 50% or with a Dk/A percentage larger than 12%. There are 33 out of the 480 utterances of the subjective test that satisfy at least one rule.

Statistical Analysis, Datasets and Supervised Classification

Iriondo, Planet, Socoró & Aliás (2007) present an experiment of emotion recognition covering different datasets and algorithms. The experiment is done

with the same corpus that is being considered in this article. Each utterance is defined by 464 attributes representing the speech signal characteristics but this first dataset is divided into different subsets to reduce its dimensionality. The experiments show almost the same results in the full dataset and in a dataset reduced to 68 parameters, so the reduced dataset is being used in this work. In this dataset, the prosody of an utterance is represented by the vectors of logarithmic F0, energy in dB and normalized durations. For each sequence, the first derivative is also calculated. Some statistics are obtained from these sequences: mean, variance, maximum, minimum, range, skewness, kurtosis, quartiles, and interquartile range. Thus, 68 parameters by utterance are computed, considering both parameters related to the pausing previously described.

In the referenced work, twelve machine learning algorithms are tested considering different datasets. All the experiments are carried out using Weka software (Witten & Frank, 2005) by means of ten-fold cross-validation. Very high recognition rates are achieved as in other previously referenced works: SMO (SVM of Weka) obtained the best results (~97%) followed by Naïve-Bayes (NB) with 94.6% and J48 (Weka Decision Tree based on C4.5) with 93.5%, considering the average of all the results. The conclusion is that, in general, the styles of the developed speech corpus can be clearly differentiated. Moreover, the results of the subjective test showed a good authenticity of the expressive speech content. However, going one step further by developing a method to validate each utterance of the corpus following subjective criteria and not only the automatic classification from the space of attributes is considered necessary.

Subjective Based Attribute Selection

The proposed approach to find the optimum classifier schema able to follow the subjective criteria consists on the development of an attribute selection method guided by the results obtained in the subjective test. Once the best schema is found it will be applied to the whole corpus in order to generate a list of candidate utterances to be pruned. Two methods for attribute selection have been developed in order to determine the subset of attributes that allows a better mapping of the subjective test results. As previously mentioned,

the original set has 68 attributes per utterance, so an exhaustive exploration of subsets is not viable and greedy search procedures will be used. On the one hand, a Forward Selection (FW) process is chosen, which starts without any attribute and adds one at a time and, on the other hand, the Backward Elimination (BW) technique is considered, which starts from the full set and deletes one attribute at a time. At each step, the classifier is tested with the 480 utterances that are considered in the subjective test, being previously trained with the 4158 remaining utterances. The wrong classified cases take part on the evaluation process of the involved subset of attributes. The novelty of this process is to use a subjective-based measure to evaluate the expected performance of the subset at each iteration. The used measure is the F1-score computed from the precision and the recall of the wrong classified utterances compared with the 33 utterances rejected by the subjective test.

Results

The process consists of six iterations: one per algorithm (SMO, NB and J48) and attribute selection technique (FW and BW). SMO algorithm obtains practically the same F1-score (~ 0.50) in both FW and BW attribute selection techniques. The results for both NB are also similar between them ($F1 \approx 0.43$). The main difference is for J48 that obtains better F1 with FW (0.45) than with BW (0.37) process. Moreover, SMO-FW seems to be the most stable configuration as it achieves almost the same result ($F1 = 0.49$) with a broad range of attribute subsets (the results are very similar with a range of attributes between 18 and 35). Results show that J48-FW has the best recall (18/33), which implies the highest number of coincidences; however the precision measure is quite low (18/51), indicating an excessive number of general misclassifications.

FUTURE TRENDS

Future work will consist on applying this automatic process over the full corpus. For instance, a ten-fold cross validation would be a good technique to cover the whole corpus. The misclassified utterances would be candidate to be pruned. A first approach would consist on running different classifiers and selecting

the final candidates by a stacking technique (Witten & Frank, 2005). Also, we will evaluate the suitability of the proposed method by performing acoustic modeling of the resulting emotional speech after pruning with respect to the results obtained with the whole corpus. A lower error on the prosodic estimation could confirm the hypothesis that it is advisable to eliminate the bad utterances of the corpus previously.

CONCLUSION

This article exposes the need of an automatic validation of an expressive speech corpus due to the impossibility of carrying out a subjective test in a large corpus. Also, an approach to achieve this goal has been presented, performing a subjective test with 30 subjects and 10 percent of the utterances, approximately. The result of this test has shown that some utterances are perceived with a dissimilar or poor expressive content with respect to their labeling. The proposed automatic classification tries to learn from the result of the subjective test in order to generalize the solution to the rest of the corpus, by means of a suitable attribute selection carried out by two different strategies (Forward Selection and Backward Elimination) using the F1-measure computed taking into account the misclassifications resulting from the subjective test as a reference.

KEY TERMS

Backward Elimination Strategy: Greedy attribute selection method that evaluates the effect of removing one attribute from a dataset. The attribute that improves the performance of the dataset when it is deleted is chosen to be removed for the next iteration. Process begins with the full set of attributes and stops when no attribute removing improves performance.

Decision Trees: Classifier consisting on an arboreal structure. A test sample is classified by evaluating it in each node, starting at the top one and choosing a specific branch depending on this evaluation. The classification of the sample is the class assigned in the bottom node.

F1-Measure: The F1-measure is an approach of combining the precision and recall measures of a classifier by means of an evenly harmonic mean of both them. Its expression is $F1\text{-measure} = (2 \times \text{precision} \times \text{recall}) / (\text{precision} + \text{recall})$.

Forward Selection Strategy: Greedy attribute selection method that evaluates the effect of adding one attribute to a dataset. The attribute that improves

the performance of the dataset is chosen to be added to the dataset for the next iteration. Process begins with no attributes and stops when adding new attributes provides no performance improvement.

Greedy Algorithm: Algorithm -usually applied to optimization problems- based on the idea of finding a global solution for a problem (despite of not being the optimal one) by choosing locally optimal solutions in different iterations.

Naïve-Bayes: Probabilistic classifier based on Baye's rule that assumes that all the pairs parameter-value that define a case are independent.

Precision: Measure that indicates the percentage of correctly classified cases of one class with regard to the number of cases that are classified (correctly or not) as members of that class. This measure says if the classifier is assuming as members of one specific class cases from other different classes.

Recall: Measure that indicates the percentage of correctly classified cases of one class with regard to the total number of cases that actually belong to this class. This measure says if the classifier is ignoring cases that should be classified as members of one specific class when doing a classification.

SVM: Acronym of Support Vector Machines. SVM are models able to distinguish members of classes whose limits are not lineal. This is possible by a non-linear transformation of input data mapping it into a higher-dimensionality space where data can be easily divided by a maximum margin hyperplane.

INTRODUCTION

Deformable models are well known examples of artificially intelligent system (AIS). They have played an important role in the challenging problem of extracting useful information about regions and **areas of interest** (ROIs) imaged through different modalities. The challenge is also in extracting boundary elements belonging to the same ROI and integrate them into a coherent and consistent model of the structure. Traditional low-level image processing techniques that consider only local information can make incorrect assumptions during this integration process and generate unfeasible object boundaries. To solve this problem, deformable models were introduced (Ivins, 1994), (McInerney, 1996), (Wang, 2000). These AI models are currently important tools in many scientific disciplines and engineering applications (Duncan, 2000).

Deformable models offer a powerful approach to accommodate the significant variability of structures within a ROI over time and across different individuals. Therefore, they are able to segment, match and track images of structures by exploiting (bottom-up) constraints derived from the image data together with (top-down) *a priori* knowledge about the location, size, and shape of these structures.

The mathematical foundations of deformable models represent the confluence of geometry, physics and approximation theory. Geometry serves to represent object shape, physics imposes constraints on how the shape may vary over space and time, and optimal approximation theory provides the formal mechanisms

for fitting the models to data. The physical interpretation views deformable models as elastic bodies which respond to applied force and constraints.

BACKGROUND

The deformable model that has attracted the most attention to date is the **active contour model** (ACM), well-known as **snakes**, presented by Kass *et al.* (Kass, 1987), (Cootes & Taylor, 1992). The mathematical basis present in snake models is similar to all deformable models, which are based on **energy minimizing** techniques.

Recently, there has been an increasing interest in level set or geodesic segmentation methods, introduced in (Osher & Sethian, 1988), (Malladi, 1995) and (Caselles, 1997). Level set approach involves solving the ACM minimization problem by the computation of minimal distances curve. This method allows topological changes within the ROIs and extension to 3D. Therefore, for some applications it is an improvement on classical ACM.

Other approaches to deformable model are those based on dynamic models or physically based techniques, for example superquadrics (Terzopoulos, 1991) and the finite element model (FEM) (Pentland, 1991). The FEM accurately describes changes in position, orientation and shape. The FEM can be used to solve fitting, interpolation or correspondence problems. In the FEM, interpolation functions are developed that allow continuous material properties, such as mass

and stiffness, to be integrated across the ROIs. This last property makes them different from the previous models and therefore more suitable for some artificial vision applications.

The next sections contain a brief introduction to the mathematical foundations of deformable models.

ENERGY MINIMIZING DEFORMABLE MODELS

Geometrically, an active contour model is a parametric contour embedded in the image plane $(x, y) \in \mathbb{R}^2$. The dynamic contour is represented as a time-varying curve, $v(s, t) = (x(s, t), y(s, t))$, where x and y are the coordinate functions and $s \in [0, 1]$ is the parametric domain. The curve evolves until the ROI, subject to constraints from a given image $I(x, y)$, reaches an equilibrium. Thus, initially a curve is set around the ROI that, via minimization of an energy functional, moves normal to itself and stops at the boundary of the ROI. The energy functional is defined as:

$$E_{snake}(s, t) = \int_0^1 [E_{internal}(v(s, t)) + E_{ext_potential}(v(s, t))] ds \quad (1)$$

The first term, $E_{internal}$, represents the internal energy of the spline curve due to mechanical properties of the contour, stretching and bending. It is a sum of two components, the elasticity and rigidity energy:

$$E_{internal}(s, t) = \left(\frac{\alpha(s, t)}{2} |v_s(s, t)|^2 + \frac{\beta(s, t)}{2} |v_{ss}(s, t)|^2 \right)$$

where α controls the tension of the contour, while β controls its rigidity. Thus, these functions determinate how the snake can stretch or bend at any point s of the spline curve. The second term couples the snake to the image:

$$E_{ext_potential}(s, t) = P(v(s, t))$$

where $P(v(s, t))$ denotes a scalar potential function defined on the image plane. It is responsible for attracting the contour towards the object in the image (external

energy). Therefore, it can be expressed as a weighted combination of energy function.

To apply snakes to images, external potentials are designed whose local minima coincides with intensity *extrema*, edges and other image features of interest. For example, the contour will be attracted to intensity edges in an image by choosing a potential

$$P(v(s, t)) = -c |\nabla [G_\sigma * I(x, y)]|$$

where c controls the magnitude of the potential, ∇ is the gradient operator and $G_\sigma * I(x, y)$, denotes the image convolved with a Gaussian smoothing filter.

In accordance with the calculus of variations, the contour $v(s, t)$ that minimizes the energy of (1) must satisfy the Euler-Lagrange equation. Moreover, the Lagrange equation of motion for a snake with the internal and external energy given by equation (1) is:

$$\mu \frac{\partial^2 v}{\partial t^2} + \gamma \frac{\partial v}{\partial t} - \frac{\partial}{\partial s} \left(\frac{\alpha(s)}{2} |v_s(s, t)|^2 \right) + \frac{\partial^2}{\partial s^2} \left(\frac{\beta(s)}{2} |v_{ss}(s, t)|^2 \right) + \nabla P(v(s, t)) = 0$$

with a mass density μ and a damping density γ . This leads to dynamic deformable models that unify the description of shape and motion, making it possible to quantify not just static shape, but also shape evolution through time. The first two terms of this partial differential equation represent inertial and damping forces. The remaining terms represent the internal stretching, the bending forces and the external forces. Equilibrium is achieved when the internal and external forces balance and the contour comes to rest, i.e., inertial and damping forces are zero, which yields the equilibrium condition.

Traditional snake models are known to be limited in several aspects, such as their sensitivity to the initial contours. These are non-free parameters and do not handle changes in the topology of the shape. That is, when considering more than one object in the image, for instance for an initial prediction of $v(s, t)$ surrounding all of them, it is not possible to detect all the objects. Special topology-handling procedures must be added. Some techniques have been proposed to solve these drawbacks. These techniques are based on information

fusion, dealing with ACM in addition to curvature driven flows and geometrical distance conditions (Solaiman, 1999), (Caselles, 1997).

GEODESIC ACTIVE CONTOUR MODEL

The geodesic active contour model is based on the computation of a minimal distances curve. Thereby, the AC evolves following the geometric heat flow equation. Let us consider a particular class of snake models in which the rigidity coefficient is set to zero, that is $\beta = 0$. Two main reasons motivate this selection: i) this will allow us to derive the relation between these energy-based active contours and geometric curve evolution ones, ii) the regularization effect on the geodesic active contours comes from curvature-based curve flows, obtained only from the other terms in equation (1). This will allow to achieve smooth curves in the proposed approach without having the high-order smoothness given by $\beta \neq 0$ in energy-based approaches.

Moreover, this smoothness component in equation (1) appears in order to minimize the total squared curvature. It is possible to prove that the curvature flow used in the geodesic model decreases the total curvature. The use of the curvature-driven curve motions as smoothing terms was proven to be very efficient. Therefore, curve smoothing will be obtained also with $\beta = 0$, having only the first regularization term. Assuming this, equation (1) may be reduced to:

$$E_{geo}(s, t) = \int_0^1 \left(\frac{\alpha(s, t)}{2} |v_s(s, t)|^2 \right) ds - \int_0^1 c |\nabla I[v(s, t)]| ds \quad (2)$$

Observe that, by minimizing the functional of equation (2), we are trying to locate the curve at the points of maxima $|\nabla I|$ (acting as edge detector) while keeping a certain smoothness in the curve (object boundary). This is actually the goal in the general formulation (equation 1) as well.

It is possible to extend equation (2), generalizing the edge detector part in the following way: let $\{g: [0, \infty[\rightarrow \mathcal{R}^+\}$ be a strictly decreasing function, which acts as a function of the image gradient used for the stopping criterion. Hence we can replace $|\nabla I|$ with $g(|\nabla I|)^2$, obtaining a general energy function:

$$E_{geo}(s, t) = \int_0^1 \left(\frac{\alpha(s, t)}{2} |v_s(s, t)|^2 \right) ds - \int_0^1 c g(|\nabla I[v(s, t)]|)^2 ds \quad (3)$$

The solution of the particular energy snake model of equation (3) is given by a geodesic curve in a Riemann space induced from the image $I(x, y)$, where a geodesic curve is a local minimal distance path between given points. To show this, the classical Maupertuis' principle from dynamical systems together with the Fermat's principle is used.

By assuming $E_{internal} = E_{ext_potential}$, it is possible to reduce the minimization of equation (1) to the following form:

$$\min_{v(s)} = \int_0^1 g(|\nabla I(x, y)|) (v(s)) \cdot |v_s(s)| ds$$

This is done by using Euler-Lagrange, and defining an embedding function of the set of curves $v(s)$, $\psi(s, t)$. That is an implicit representation of $v(s)$, assuming that $v(s)$ is a level set of a function $\psi(s, t): [0, a] \times [0, b] \rightarrow \mathcal{R}$, the following equation for curve/surface evolution is derived:

$$\frac{\partial \psi}{\partial t} = g(\nabla I)(C + K) |\nabla \psi|$$

where C is a positive real constant and K is the Euclidean curvature in the direction of the normal.

To summarize the force $(C+K)$ acts as the internal force in the classical energy-based snake model, smoothness being provided by the curvature part of the flow. The heat-flow K ψ is the regularization curvature flow that replaces the second order smoothness term in equation (1). The external-image dependent force is given by the stopping function, $g(I)$. Thus this function stops the evolving curve when it arrives at the object's boundaries.

The advantage of using a level set is that one can perform numerical computations involving curves and surfaces on a fixed Cartesian grid without having to parameterize these objects (this is called the *Eulerian approach*). Moreover, level set representation can handle topological shape changes as the surface evolves and it is less sensitive to initialisation. Figure 1 shows

the results of the level set approach applied to a biomedical colour image. Figure 1.a) shows the original image, b) show the initialization, which is composed by multiple curves. This is also an advantage over the classical ACM. Figure 1.c) shows the results after 50 iterations and d) show the final ROI detection.

Figure 2 shows different results for ROI detection in **biomedical images** with the geodesic active contour model. Column (a) and (c) show the original image and (b) and (d) the final segmentation result.

The model is efficient in time and accuracy. However, there are also some drawbacks in terms of effi-

ciency and convergence. It has non-free parameters, ψ is dependent of the time step, Δt , and the spatial one.

DEFORMABLE FINITE ELEMENT MODEL

A powerful approach to computing the local minima of a functional such as equation (1) is to construct a dynamical system that is governed by the energy minimization function and allows the system to evolve to equilibrium.

Figure 1. Geodesic active contour model with multiple initializations

Figure 2. Results of ROI detection with the geodesic active contour model

In order to compute a minimum energy solution numerically, it is necessary to discretize the energy (1). Thus, the continuous model, v is represented in discrete form by a vector U of shape parameters associated with the local-support basis functions. The discretized version of the Lagrangian dynamics equation may be written as a set of second-order ordinary differential equations for the discrete nodal points displacements U , that is a vector of the $(\Delta x, \Delta y, \Delta z)$ displacements of the n nodal points that represents the ROI, thus:

$$M\ddot{U} + C\dot{U} + KU = \vec{F} \quad (4)$$

That is the governing equation of the physical model, which is characterized by its mass matrix M , its stiffness matrix K and its dumping matrix C and the vector on the right hand side is describing the x , y , and z components of the forces acting on the nodes. Equation (4) is known as the governing equation in the FEM method, and may be interpreted as assigning a certain mass to each nodal point and a certain material stiffness and damping between nodal points.

The main drawback of the FEM is the large computational expense. Another important problem when using the FEM for vision is that all the degrees of freedom are coupled. Therefore, closed-form solutions are not possible. In order to solve the problem the system may be diagonalized by means of a linear transform into the vibration modal space of the mesh modelling the ROI (Pentland, 1991). Thus, vector U is transformed by a matrix P derived from the free vibrations modes of the equilibrium equation. Therefore, an eigenvalue problem can be derived with the basis set of eigensolutions composed by $\{w_i, \omega_i\}$. The eigenvector w_i is called

the i^{th} mode's shape vector and ω_i is the corresponding frequency of vibration. Each eigenvector w_i consists of the (x, y, z) displacement for each mode that parameterize the ROI. Usually the basis set is reduced by its Karhunen-Loeve (KL) expansion.

The model maybe also extended to contain a set of ROIs. Thus, for a given image in a training set, a vector containing the largest vibration modes describing the different deformable ROI surfaces is created. This random vector may be statistically constrained by retaining the most significant variation modes of its KL expansion on the image data set. By these means, the conjunction of ROI surfaces may be deformed according to the variability observed in the training set.

Figure 3 shows the results of the FEM model applied to a brain **magnetic resonance** image and a lung computed **tomography** image. Figure 3.a) shows the original structure inside the initial mesh surface and b) show the model obtained after evolve the spherical mesh by means of equation (3). Figure 3. c) shows the original lung structure and d) the final model when using also a spherical mesh as initial surface.

FUTURE TRENDS

Deformable models are suitable for different applications and domains such as computer vision, computational fluid dynamics, computer graphics and biomechanics. However, each model usually is application dependent and further improvements and processing of the model should be done to achieve satisfactory results. Techniques based on region properties, fuzzy logic theory and combination of different models have

Figure 3. Results of the FEM model

already been suggested (Ray, 2001), (Bueno, 2004), (Yu, 2002), (Bridson, 2005).

Moreover, these techniques have been broadly used to model real life phenomena, like fire, water, cloth, fracturing materials, etc. Results and models from these research areas may be of practical significance if they are applied in Artificial Vision.

CONCLUSION

Energy minimizing active models has been shown to be a powerful technique to detect, track and model interfaces and shapes of ROIs. Since the work on ACM by (Kass, 1987) energy minimizing active models have been applied and improved by using different mathematical and physical techniques. The most promising models are those presented here: the geodesic and the FEM one for ROI tracking and modeling respectively.

The models are suitable for color and 3D images. The geodesic model may handle topological changes on the ROI surface and is not sensitive to initialization. The FEM model may represent the relative location of different ROI surfaces and it is able to accommodate their significant variability across different images of the ROI. The surfaces of each ROI are parameterized by the amplitudes of the vibration modes of a deformable geometrical mesh, which can handle small rotations and translations. However, as mentioned before there is still room for further improvements within these models.

KEY TERMS

Active Model: It is a numerical technique for tracking interfaces and shapes based on partial differential equations. The model is a curve or surface which iteratively deforms to fit to an object in an image.

Conventional Mathematical Modeling: The applied science of creating computerized models. That is a theoretical construct that represents a system composed by set of region of interest, with a set of parameters, both variables together with logical and quantitative relationships between them, by means of mathematical language to describe the behavior of the system. Parameters are determined by finding a curve in 2D or a surface in 3D, each patch of which is defined by a net of curves in two parametric directions, which matches a series of data points and possibly other constraints.

Finite Element Method: Numerical technique used for finding approximate solution of partial differential equations (PDE) as well as of integral equations. The solution approach is based either on eliminating the differential equation completely (steady state problems), or rendering the PDE into an equivalent ordinary differential equation, which is then solved using standard techniques such as finite differences.

Geodesic Curve: In presence of a metric, geodesics are defined to be (locally) the shortest path between points on the space. In the presence of an affine connection, geodesics are defined to be curves whose tangent vectors remain parallel if they are transported along it. Geodesics describe the motion of point particles.

Karhunen-Loeve: Mathematical techniques equivalent to Principal Component Analysis transform aiming to reduce multidimensional data sets to lower dimensions for analysis of their variance.

Modal Analysis: Study of the dynamic properties and response of structures and or fluids under vibrational excitation. Typical excitation signals can be classed as impulse, broadband, swept sine, chirp, and possibly others. The resulting response will show one or more resonances, whose characteristic mass, frequency and damping can be estimated from the measurements.

Tracking: Tracking is the process of locating a moving object (or several ones) in time. An algorithm analyses the image sequence and outputs the location of moving targets within the image. There are two major components of a visual tracking system; *Target Representation and Localization* and *Filtering and Data Association*. The 1st one is mostly a bottom-up process which involve segmentation and matching. The 2nd one is mostly a top-down process, which involves incorporating prior information about the scene or object, dealing with object dynamics, and evaluation of different hypotheses.

Ensemble of ANN for Traffic Sign Recognition

INTRODUCTION

“Machine Learning (ML) is the subfield of Artificial Intelligence conceived with the bold objective to develop computational methods that would implement various forms of learning, in particular mechanisms capable of inducing knowledge from examples or data” (Kubat, Bratko & Michalski, 1998, p. 3).

The simplest and best-understood ML task is known as supervised learning. In supervised learning, each example consists of a vector of features (\mathbf{x}) and a class (y). The goal of the learning algorithm is, given a set of examples and their classes, find a function, f , that can be applied to assign the correct class to new examples. When the function f takes values from a discrete set of classes $\{C_1, \dots, C_K\}$, f is called a *classifier* (Dietterich, 2002).

In the last decades it has been proved that learning tasks in which the unknown function f takes more than two values (multi-class learning problems) the better approach is to decompose the problem into multiple two-class classification problems (Ou & Murphey, 2007) (Dietterich, & Bakiri, 1995) (Massulli & Valentini, 2000).

This article describes the implementation of a system whose main task is to classify prohibition road signs into several categories. In order to reduce the learning problem complexity and to improve the classification performance, the system is composed by a collection (ensemble) of independent binary classifiers. In the proposed approach, each binary classifier is a single-

output neural network (NN) trained to distinguish a particular road sign kind from the others.

The proposed system is a part of a Driver Support System (DSS) supported by the Spanish Government under project TRA2004-07441-C03-C02. For this reason, one of the main system requirements is that it should be implemented in hardware in order to use it aboard a vehicle for real time categorization. In order to fulfill this constraint, a reduction in the number of features that describe the instances must be performed. As consequence if we have k generic road sign types we will use k binary NN and k feature selection process will be executed.

BACKGROUND

It is known that road signs carry essential information for safe driving. Among other things, they permit or prohibit certain maneuvers, warn about risk factors, set speed limits and provide information about directions, destinations, etc. Therefore, road sign recognition is an essential task for the development of an autonomous Driver Support System.

In spite of the increasing interest in the last years, traffic sign recognition is one of the less studied subjects in the field of Intelligent Transport Systems. Approaches in this area have been mainly focused on the resolution of other problems, such as road border detection (Dickmanns & Zapp, 1986) (Pomerlau & Jochem, 1996) or the recognition of obstacles in the

vehicle's path such as pedestrians (Franke, Gavrilla, Görxig, Lindner, Paetzold & Wöhler, 1998) (Handmann, Kalinke, Tzomakas, Werner & Seelen, 1999) or other vehicles (Bertozzy & Broggi, 1998).

When the number of road sign types is large, road sign recognition task is separated in two processes: detection and classification. Detection process is responsible for the localization and extraction of the potential signs from images captured by cameras. Only when the potential signs have been detected they can be classified as one of the available road sign-types.

In the published researches, detection is based on color and/or shape of traffic signs (Lalonde & Li, 1995). On the other hand, to solve the classification task several ML algorithms have been used. Among the used techniques it is worth mentioning: The Markov Model (Hsien & Chen, 2003), Artificial Neural Networks (Escalera, Moreno, Salich & Armingol, 1997) (Yang, Liu & Huang, 2003), Ring Partitioned Method (Soetedjo & Yammada 2005), the Matching Pursuit Filter (Hsu & Huang 2001) or the Laplace Kernel classifier (Paclík, Novovicová, Pudil, & Somol, 1999).

A NEURAL NETWORK BASED SYSTEM FOR TRAFFIC SIGN RECOGNITION

In this work, we present the architecture of a system whose task is to classify prohibition road signs into several categories. This task can be described as a supervised learning problem in which the input information comes from a set of road signs arranged in a fixed number of categories (classes) and the goal is to extract, from the input data, the real knowledge needed to classify correctly new signs.

The proposed system is a Multilayer Perceptron (MLP) based classifier trained with the Back-Propagation algorithm. In order to integrate this classification system into a DSS capable to perform real-time traffic sign categorization, a hardware implementation on Field Programmable Gate Array (FPGA) is necessary.

With the aim of reducing the problem complexity, an ensemble of specialized neural networks is proposed. In addition and due to the strict size limitations of ANN implementation on FPGAs (Zhu & Sutton, 2003) the construction of each specialized MLP is combined with a specific reduction in the number of features that describes the examples.

Traffic Sign Pre-Processing

Since the signs to be classified are embodied in images acquired by a camera attached to a moving vehicle, it can be assumed that the signs have a varying size (signs get bigger as the vehicle moves toward them). Therefore, once the traffic signs have been detected, the first step is to normalize them to a specific size. The aim of this process is to ensure that all the signs (examples) are described by the same number of pixels (features). In our approach we have used 32x32 pixel signs.

Once the signs have been normalized, a grayscale conversion is performed. Since the original images are represented in the RGB (Red, Green and Blue) color space, this conversion is done by adding the red, green and blue values for each pixel and dividing by three. As result of both processes, each road sign is transformed into a 1024 element vector in which each pixel is represented by a real number in the range [0.0, 1.0].

System Architecture

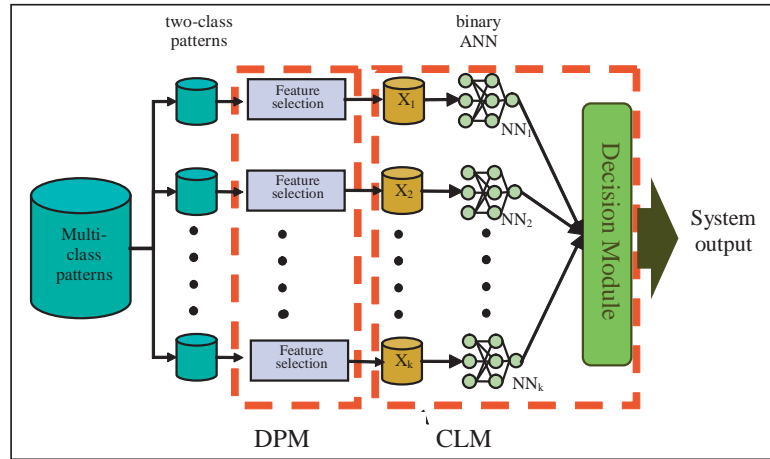

The general framework of the proposed system (Figure 1) is composed of two modules: the *Data Preprocessing Module* (DPM) and the *Classification Module* (CLM). The DPMs function is to select from among the 1024 attributes that describe a sign the subset that each specialized neural network inside the CLM must receive. On the other hand, the CLMs function is to classify each input data set as one of the available prohibition road sign-types. Since this module is composed of several independent classifiers, in order to obtain the final classification, an integration of the individual predictions is required.

To build both, the DPM and the CLM, a new data encoding schema is necessary. In particular, the multi-class problem has to be decomposed into a set of binary subproblems.

Data Preprocessing Module

Practical experience shows that using as much as possible input information (features) does not imply higher output accuracy. Feature subset selection (Witten & Frank, 2005) (Hall, 1998) is the procedure of selecting just the relevant information, avoiding irrelevant and redundant information and reducing the learning task dimensionality.

Figure 1. General framework of the proposed architecture

The proposed architecture adopts a model in which the feature subset that describes an example is not unique but depends on the task associated to each classifier. In other words, since the classification problem is divided in k binary sub-problems, k feature selection procedures are necessary.

In this work, the feature selection module has been built using the Weka tool (Witten & Frank, 2005). At first, several feature selection algorithms from those included in Weka were considered (Sesmero, Alonso-Weber, Gutiérrez, Ledezma & Sanchis, 2007). After analyzing both, the feature set size and the experimental results, combination of Best First (Russell & Norvig, 2003) and Correlation-based Feature Selection (Hall, 1998) was selected as base for the DPM construction.

Classification Module

The Classification Module is based on an One Against All (OAA) model. In this modeling, the final classifier is composed of a collection of binary classifiers where each of them is specialized in discriminating a specific road sign type from the others. Therefore, for a classification problem where k road sign types have to be separated, this approach results in a system in which for each existing class a different NN is used.

Decomposing the global classifier into a set of independent NN not only reduces the complexity problem but also permits that the DPM is able to select the most significant attribute set for each binary classification

task. In addition, each NN can have its own architecture (number of hidden nodes, activation function, learning rate, etc) and since there is no connection between the individual networks, the training can be performed distributing the work on several processors.

ANNs Output Combination

Once the binary NN's have been trained the global classifier system can be generated. However, since each classifier makes its own prediction, a decision module that integrates the results from the set of classifiers and produces a unique final classification is required. Experimentally it is found that, for the proposed classification task, the most efficient decision criterion is selecting the NN with the highest output value. Therefore, the formula used in the decision module is:

$$f(\bar{x}, f_1, f_2, \dots, f_k) = \arg \max_{i=1, \dots, k} (f_i) \quad (1)$$

where f_i is the output value of the neural network associated to the i -th class.

Classification Process

When the system receives an unlabeled road sign to be classified in some of the fixed categories, such sign is sent to each classifier's input module. The DPM selects the pixel subset according to its relevant attribute list. The chosen pixels are used as the input for the asso-

ciated ANN, which applies its knowledge to make a prediction. The individual predictions are sent to the decision module that carries out an integration of the received information and produces a unique final classification. This process is shown in Figure 2.

Empirical Evaluation

The proposed system has been validated over 5000 examples arranged in ten generic kinds of prohibition road signs: no pedestrians, no left/right turn ahead, no stopping and no parking, no overtaking, and 20-30-40-50-60 and 100 km speed limits.

In order to evaluate our approach, three classification methods have been compared:

- The direct multi-class approach,
- The OAA approach with the full feature space and,
- The OAA approach with feature selection.

In the direct multi-class approach (experiment 1), the classification problem has been solved with a MLP with 1024 (32×32) input nodes, one hidden layer with 50 neurons and one output layer with 10 neurons. In this approach the class associated to each learning pattern is encoded using a vector C , which has as many components c_i as existing class (10). The component value c_i will be 1 if the sign belongs to class i , and 0 in any other case.

In the OAA approach with the full feature space (experiment 2) the previous net is split into ten binary ANN. In other words, this approach uses 10 binary

MLP with 1024 input nodes, 36 hidden nodes and 1 output node.

Finally, in the OAA approach with Feature Selection (experiment 3), the problem is solved with an ensemble containing 10 binary MLP with 36 hidden nodes in each. The number of input units and, therefore, the feature space used by each ANN is determined by the DPM. This number is shown in Table 1.

In order to build the binary classifiers used in the last two experiments, a new class encoding schema is necessary. In both cases, the class associated with each pattern is encoded using a bit. Since in both experiments, the i -th binary classifier is trained to distinguish the class i from all the other class, the new encoding is equivalent to select the c_i component from the previous codification.

In Table 2 we show the estimate classification accuracy for the described experiments when a 10-fold cross validation process is used.

The experimental evaluation reflects that splitting the classification task into binary subtasks (experiment 2) increases the classification accuracy.

On the other hand, the loss of classification accuracy when the feature selection process is performed (experiment 3) is not very significant compared with the benefits of the drastic input data reduction.

FUTURE TRENDS

The future work will be mainly focused on extending the system in order to cope with regulatory, warning, indication, etc, signs, i.e, with a bigger number of classes. This task will allow us to investigate and de-

Figure 2. Classification process

Table 1. Number of selected features; in the first column appears the label of each class

| Class | Prohibition road sign | Number of selected features |
|-------|-----------------------------|-----------------------------|
| C1 | no pedestrians | 116 |
| C2 | no (left, right) turn ahead | 91 |
| C3 | stopping and no parking | 44 |
| C4 | no passing | 114 |
| C5 | 60 km speed limit | 114 |
| C6 | 50 km speed limit | 110 |
| C7 | 40 km speed limit | 100 |
| C8 | 30 km speed limit | 114 |
| C9 | 20 km speed limit | 103 |
| C10 | 100 km speed limit | 87 |

Table 2. Summary of estimate classification accuracy (percentage)

| Experiment | C1 | C2 | C3 | C4 | C5 | C6 | C7 | C8 | C9 | C10 | Global |

| 3 | 100 | 100 | 98,0 | 100 | 92,0 | 96,0 | 88,0 | 100 | 98,0 | 98,0 | 97,0 |

velop new procedures that will contribute to the design of a more versatile system.

In the design of this new system, other multi-class approach such as the One Against Higher Order Modeling (Lu & Ito, 1999) and the Error-Correction Output Code (Dietterich & Bakiri, 1995) would be analyzed.

CONCLUSION

In this work, an architecture for traffic sign classification has been described. The software implementation shows very high recognition rates. For this reason this architecture can be considered as a good solution for the traffic sign classification problem.

Moreover, the features of this architecture make it possible to implement this system on FPGAs and, therefore, to use it in real-time applications.
